Abstract. National and European legislation over the past 20 yr, and the modernisation or removal of industrial sources, have significantly reduced European ozone precursor emissions. This study quantifies observed and modelled European ozone annual and seasonal linear trends from 158 harmonised rural background monitoring stations over a constant time period of a decade (1996–2005). Mean ozone concentrations are investigated, in addition to the ozone 5th percentiles as a measure of the baseline or background conditions, and the 95th percentiles that are representative of the peak concentration levels. This study aims to characterise and quantify surface European ozone concentrations and trends and assess the impact of the changing anthropogenic emission tracers on the observed and modelled trends.

Significant ($p < 0.1$) positive annual trends in ozone mean, 5th and 95th percentiles are observed at 54%, 52% and 45% of sites respectively (85 sites, 82 sites and 71 sites). Spatially, sites in central and north-western Europe tend to display positive annual ozone trends in mean, 5th and 95th percentiles. Significant negative annual trends in ozone mean 5th and 95th percentiles are observed at 11%, 12% and 12% of sites respectively (18 sites, 19 sites and 19 sites) which tend to be located in the eastern and south-western extremities of Europe. European-averaged annual trends have been calculated from the 158 sites in this study. Overall there is a net positive annual trend in ob-

served ozone mean (0.16 ± 0.02 ppbv yr⁻¹ (2σ error)), 5th (0.13 ± 0.02 ppbv yr⁻¹) and 95th (0.16 ± 0.03 ppbv yr⁻¹) percentiles, representative of positive trends in mean, baseline and peak ozone. Assessing the sensitivity of the derived overall trends to the constituent years shows that the European heatwave year of 2003 has significant positive influence and 1998 the converse effect; demonstrating the masking effect of inter-annual variability on decadal based ozone trends.

The European scale 3-D CTM CHIMERE was used to simulate hourly O₃ concentrations for the period 1996–2005. Comparisons between the 158 observed ozone trends to those equivalent sites extracted from regional simulations by CHIMERE better match the observed increasing annual ozone (predominantly in central and north-western Europe) for 5th percentiles, than for mean or 95th ozone percentiles. The European-averaged annual ozone trend in CHIMERE 5th percentiles (0.13 ± 0.01 ppbv yr⁻¹) matches the corresponding observed trend extremely well, but displays a negative trend for the 95th percentile (-0.03 ± 0.02 ppbv yr⁻¹) where a positive ozone trend is observed. Inspection of the EU-averaged monthly means of ozone shows that the CHIMERE model is overestimating the summer month O₃ levels.

In comparison to trends in EMEP emissions inventories, with the exception of Austria-Hungary, we do not find that anthropogenic NO_x and VOC reductions have a substantial

effect on observed annual mean O₃ trends in the rest of Europe. On a ten year time-scale presented in this study, O₃ trends related to anthropogenic NO_x and VOC reductions are being masked as a result of a number of factors including meteorological variability, changes in background ozone and shifts in source patterns.

1 Introduction

Ozone is central to the chemistry of the troposphere owing to its role in the initiation of photochemical oxidation processes via photolysis and subsequent reactions of the photo-products to form the hydroxyl radical (Monks, 2005). Tropospheric ozone is also recognised to be a threat to human health (WHO, 2003), have a deleterious impact on vegetation (Fowler et al., 1999, 2009) as well as being an important tropospheric greenhouse gas (IPCC, 2007). Tropospheric ozone is a secondary pollutant formed from the chemistry of the nitrogen oxides and volatile organic compounds (VOCs) (Monks, 2005).

Throughout the whole troposphere the concentrations of ozone have changed in the modern era characterised by the enhanced emissions of precursors from industrialisation. Analysis of historical ozone records indicate that tropospheric ozone levels in both hemispheres have increased by a factor of 3 to 4 over the recent centuries (Anfossi et al., 1991; Pavelin et al., 1999; Sandroni et al., 1992; Staehelin et al., 1994; Volz and Kley, 1988).

The tropospheric ozone budget at any given place is a complex combination of photochemical processes and physical processes, i.e. photochemical production or destruction of ozone, stratospheric-tropospheric exchange (STE) and destruction of ozone at the Earth's surface.

Quantitative establishment of temporal ozone trends is important for quantifying the impact of changing precursor emissions and also from the perspective of local and regional air quality control in terms of import/export of ozone and the amount that is locally or regionally controllable. Observed ozone trends are a challenge to interpret as there are a number of possible factors responsible (Cape, 2008) such as (a) changes in anthropogenic emissions of precursors (both regional and global), (b) effects of variable precursor emissions from biomass burning (both regional and global), (c) changes in stratosphere-troposphere exchange trends, (d) changes in geographical emission patterns and (e) changes in air-mass transport patterns. Long-term series of high quality data are required in order to detect the trend amongst the large inter annual variation. Jonson et al. (2006) have discussed many of these effects in relation to ozone trends.

There has been substantial focus to date on quantifying hemispheric “background” trends in ozone (The Royal Society, 2008). There are different definitions of background (Chan and Vet, 2010; Parrish et al., 2009; The Royal Soci-

ety, 2008) but a pragmatic definition is that it is ozone measured at a site without the influence of strong local effects. This leads to a hierarchy of background measurements from hemispheric background, to regional, rural and urban. Much of the focus in hemispheric background trends has been on the detection and attribution of ozone trends in marine air entering the western seaboard of the USA/Canada and Europe (Carslaw, 2005; Chan and Vet, 2010; Cooper et al., 2010a; Derwent et al., 2007a; Jaffe and Ray, 2007; Law et al., 2010; Council, 2009; Oltmans et al., 2006; Parrish et al., 2009; Simmonds et al., 2004). Measurements of marine inflow can provide the opportunity to sample ozone in an environment without the confounding influence of continental emissions while at the same time having acted as an integrator of up-wind continental-scale emissions. It is worth noting that marine in-flow measurements could be influenced by the effects of recirculation of downwind continental air over the oceans associated with synoptic-scale systems. There remains some discussion as to the attribution of the observed trends (Oltmans et al., 2006, 2008; Parrish et al., 2009; Cooper et al., 2010b).

A review of Northern Hemisphere ground-based “background” ozone trends (including several European sites) has shown a slowly increasing average ozone concentration in the Northern Hemisphere of 0.5–2% yr⁻¹ (variable uncertainties Vingarzan (2004) and references therein). Long-term European background ozone trends of 1.5±0.9% yr⁻¹ at Hohenpeissenberg (1971–1983) (Logan, 1985), 1.48±0.51% yr⁻¹ at Zugspitze (1978–1995) (Oltmans et al., 1998), 0.31±0.12 ppbv yr⁻¹ at Mace Head (1987–2007) (Derwent et al., 2007b) have been observed, with more recent annual ozone trends at background European sites summarised by country in Table 1. Many previous studies investigate O₃ trends at a single or small number of sites. Where available, the annual trends (ppbv yr⁻¹ or % yr⁻¹) of individual sites has been averaged from literature values with statistical significance ($p < 0.1$) to ascertain an average trend by country. Values reported from this study in Table 1 are the average of annual trends (ppbv yr⁻¹ and % yr⁻¹) calculated for individual sites within each country with statistically significant trends ($p < 0.1$). The period of trend analysis varies in each case study, rendering it difficult to compare all sites in a uniform manner. Despite the increasing ozone trends in the northern hemisphere, the upward trends appear to be continuing at a reduced rate since the 1980s (Guicherit and Roemer, 2000).

In many respects continental/regional trends are more difficult to characterise owing to a greater number of competing effects. Jenkin (2008) concluded from an analysis of UK ozone data that the observations at a given location were influenced by a combination of global/hemispheric, regional- and local-scale effects with the net trend being dependent on the relative influence of these contributions which can vary spatially and temporally. For the UK, he noted three major influences (i) a gradual increase in

Fig. 1. A schematic diagram of an idealized marine background and European continental ozone seasonal cycle.

the hemispheric baseline ozone concentration resulting from global-scale effects, thereby influencing the baseline levels of ozone brought into the UK from the Atlantic Ocean; (ii) substantial short-term elevations in ozone concentrations during summertime episodes, resulting from the formation of additional ozone from regional-scale photochemical processing of emitted VOC and NO_x over north-west Europe, and (iii) local-scale removal of ozone by direct reaction with emitted NO has gradually decreased, as a result of the control of NO_x emissions.

Figure 1 is a schematic diagram of an idealized marine background and European continental ozone seasonal cycle. In winter, there is an ozone decrement over continental Europe below the nominal marine background driven by the suppression of ozone levels by NO. In general, reductions in urban NO_x may lead to an increase in wintertime urban and regional ozone. The origin and occurrence of springtime ozone maximum has been discussed in Monks (2000). In summer, the period of highest photochemical activity there is a substantial ozone increment over marine background controllable by precursor reductions. Seasonal trends can give insight into the relative contribution of photochemical ozone production/peak episodes (summer/95th percentile), NO_x titration (winter) and the hemispheric background (5th percentile).

Much legislation over the past 20 yr, for example the European Directive 2008/50/EC (2008), has focused on the reduction of ozone precursor emissions in Europe. Emission inventories (Monks et al., 2009; Vestreng et al., 2009) show a downward trend in emissions (Fig. 2) in Europe which seems to be matched on the whole by observations of the precursor species (Derwent et al., 2003; EEA, 2007; von Schneidmesser et al., 2010). The mapping of these emission trends to models and observations remains a challenge

Fig. 2. The average anthropogenic NO_x and NMVOC emissions (from the EMEP emission inventory) 1980–2008 for the 158 sites used in this study.

(Jonson et al., 2006), particularly the ability to pull out relatively smaller trends from inter-annual variability (Koumoutsaris et al., 2008; Voulgarakis et al., 2010). Derwent et al. (2010) carried out sensitivity studies with a photochemical trajectory model to show how European reductions in VOC and NO_x levels would have been the cause of reductions in episodic peak ozone levels. Models (Derwent et al., 2010; Szopa et al., 2006) have also shown that the benefit of European emission control measures can be significantly counterbalanced by increasing background ozone levels and subsequent long range transport, as both are of the same magnitude (up to 4 ppbv) but opposite in sign coupled to nonlinearities in the photochemical ozone formation. The impact of long-range transport of ozone and its precursors on European ozone concentrations are of significant policy concern (Keating and Zuber, 2007).

The amount of regional-scale work on ozone trends is substantially smaller than that on hemispheric trends. There has been regional-scale work in the USA and Canada (Chan and Vet, 2010; Cooper et al., 2010b; Fiore et al., 2002; Jaffe and Ray, 2007) Japan (Tanimoto et al., 2009), China (Xu et al., 2008) and often on a country-scale within Europe based on a representative site (recent examples in Table 1). There are few studies that have investigated regional scale trends in a self-consistent manner across Europe (see Jonson et al., 2006; Solberg et al., 2009; Vautard et al., 2006).

The work in this paper details observed and modelled regional European ozone trends. A harmonised observational ozone data set from a constant time period of a decade (1996–2005) is used for trend calculation using consistent data analysis techniques. Not only are mean ozone concentrations investigated, but also the ozone 5th percentiles which can be a measure of the baseline or background conditions, in addition to the 95th percentiles that are representative of

Fig. 3. Locations of the 158 measurement stations used in this study.

the peak concentration levels. Both the annual and seasonal variability are explored to decompose potential photochemical and non-photochemical influences. The study aims to characterise and quantify surface European ozone concentrations and trends and assess the impact of the changing anthropogenic emission tracers on the observed and modelled trends.

2 Data selection and methodology

The data used in the trend analysis originates from the the GEOmon project (Global Earth Observation and MONitoring, <http://www.geomon.eu/>) harmonised data set of trace gases from 397 ground-based measurement stations representative of rural, suburban and urban European environments. These stations belong to a variety of regional, national and European air quality networks (e.g. EMEP, GAW, Airbase and some national network stations).

The harmonised trace gas data set, available from the GEOmon distributed database, provides one ASCII file per site of hourly O_3 , NO_2 and CO data covering the time period of 1996–2006 inclusive (<http://geomon.nilu.no/>). Each file has unified and consistent time stamps in UTC, the conversion of data to units of volume mixing ratio (ppbv), a uniform data flagging system for quality assurance, details of the data source and consistent data formatting to facilitate site comparisons across Europe.

158 sites categorised as rural/background (not directly impacted by nearby precursor emissions), with O_3 data available between 1996–2006, were selected for analysis from the overall data set (see Fig. 3 and Table C1 in the Supplement). The majority of these sites have a continuous time series for the 1996–2005 inclusive period. The selection criteria was a maximum of one year with less than 75 % of data and more than 75 % of the data for all other years.

These sites have been assessed in terms of their representativeness and recategorised accordingly (Henne et al., 2010) (Table C1 in the Supplement), allowing a characterisation of continental-scale O_3 trends. The advantage of this approach at the continental-scale, is the use of a large number of sites which are less influenced by measurement/sampling bias of any single site. The majority of sites are located within central Europe, due to a lack of long-term monitoring sites within France, Spain and the Mediterranean region within the monitoring networks used to compile the GEOmon harmonised dataset. Although the data used within this study may be biased towards Central European locations, the individual sites selected are representative of rural and/or background O_3 sites (with the exception of BE0211A, BE0345A, DE0754A, GB0033R, NL0223A, NL0232A that are recategorised as suburban) and are categorised in full within Table C1 in the Supplement.

A variety of tools have been developed to assess the ozone trends using the statistical programming language R (R Development Core Team, 2009). Decadal and seasonally disaggregated O_3 trends have been characterised using the non-parametric loess regression (Cleveland, 1979) to fit more complex trends of daily and monthly O_3 concentrations with at least 75 % data coverage. To identify changes in mean, background and peak O_3 , the openair package (Carslaw and Ropkins, 2009) was used to deseasonalise O_3 time series (using an stl-based method Cleveland et al., 1990), and quantify linear trends (combining the non-parametric Mann-Kendall analysis for trend (Hirsch et al., 1982) with Sen-Theil slope estimates) of monthly means, 5th and 95th percentiles, respectively. Linear trends were also quantified in units of $\% \text{ yr}^{-1}$ from log-transformed (Parrish et al., 2002; Parrish, 2006) data. Annual and seasonal trends are reported including 95 % confidence intervals. The uncertainty of European-averaged annual trends in ozone are reported with 2σ errors (σ_T) calculated through error propagation from the individual trend uncertainties (σ_t) using Equation 1, where N is the total number of observed sites in this study (158 sites).

$$\sigma_T = \frac{\sqrt{\sum \sigma_t^2}}{N} \quad (1)$$

The statistical uncertainties quoted in this paper must also be convolved with systematic uncertainties typical for the UV absorption measurement of ozone. Generally, O_3 data sets of this variety are believed to be accurate to within $\pm 3\%$.

3 Results

There are a number of factors that affect the ability to detect a trend (Weatherhead et al., 1998, 2002) that include:

- (a) measurement uncertainty
- (b) long-term stability of the measurements

Fig. 4. Examples of categorised loess trends of observed monthly mean O_3 (ppbv yr^{-1}) (all sites available in Fig. A1 of the Supplement) displaying no trend (top left), increasing trend (top middle), decreasing trend (top right), increasing then decreasing trend (bottom left), decreasing then increasing trend (bottom middle right) and a complex trend (bottom right). Circles = monthly mean, squares = annual 5th percentile, triangle = annual 95th percentile, grey line = loess trend of monthly mean.

- (c) autocorrelation
- (d) natural variability
- (e) extreme events e.g. heatwaves

In general, the number of years required to detect a trend is dependent on the magnitude of the variance and the autocorrelation coefficient of the noise (Weatherhead et al., 1998).

A number of statistical methods have historically been used to quantify trends in ozone and other environmental datasets, the simplest and most commonly used is a linear regression of which methods are reviewed in Hess et al. (2001). Whilst a loess regression and autoregressive integrated moving average (Tripathi et al., 2010; Oltmans et al., 2008) sometimes combined with a cubic polynomial fit (Oltmans et al., 2008) have been used to highlight and characterise seasonality and longer term variations in ozone time-series. Trend tests include t-test and Mann-Kendall (Hirsch et al., 1982; Sicard et al., 2009, 2010). Loess regression is a non-parametric method that can be used to derive a good fit and characterisation of complex time-series that have a seasonal component such as ozone, however the trend is not readily quantifiable. Consequently, a Mann-Kendall trend test is used to quantify linear trends over the ten year time period in this study.

In this work an ensemble approach has been developed using 158 sites and may drive the variance down for trend detection but will not offset the influence of meteorological variability. Further, the ensemble is taken from sites that pass the data availability and quality thresholds for this work and has spatial limitations (Fig. 3).

3.1 Characterisation of annual European ozone trends

Visual inspection of the loess trends in monthly mean O_3 over the period of 1996–2005 (inclusive) show six different forms of temporal evolution (see Fig. 4) namely, (i) no trend, (ii) positive trend, (iii) negative trend, (iv) increasing then decreasing concentrations, (v) decreasing then increasing concentrations and (vi) complex behaviour. Individual plots for all sites are available in Fig. A1 of the Supplement. Each site was categorised accordingly (Table 2, summarised from Table A1 from the Supplement), with the majority (97 sites) exhibiting no apparent loess trends in O_3 . 30 of the 158 sites exhibit positive O_3 loess trends, all of which show increasing annual O_3 5th and/or 95th percentiles. 8 sites, located in eastern, north-eastern and south-western Europe, were characterised with negative O_3 loess trends all with declining annual 5th and/or 95th O_3 percentiles. A total of 14 sites were categorised with more complex O_3 loess trends, 4 of which are located in the UK.

Quantification of the more simplistic linear trend shows that 85 of the 158 sites, the majority of which are located in north-western and central Europe, display significant ($p < 0.1$) positive linear trends in monthly mean O_3 (Fig. 5 and Table A2 in the Supplement), with a range of 0.11 to $1.05 \text{ ppbv yr}^{-1}$ (0.34 to 6.05 \% yr^{-1}). Especially high trends are noted in several Austrian sites, with trends of $> 1 \text{ ppbv yr}^{-1}$ for AT0154 (Wiesmath) and AT0167 (Payerbach) observed at IT04 (Ispra) located within the Po Valley, a region of high anthropogenic emissions and static meteorology (Finzi and Lechi, 1991; Henne et al., 2010). Significant ($p < 0.1$) negative linear trends in mean O_3 are identified at 18 sites, with a range of -0.16 to $-1.28 \text{ ppbv yr}^{-1}$

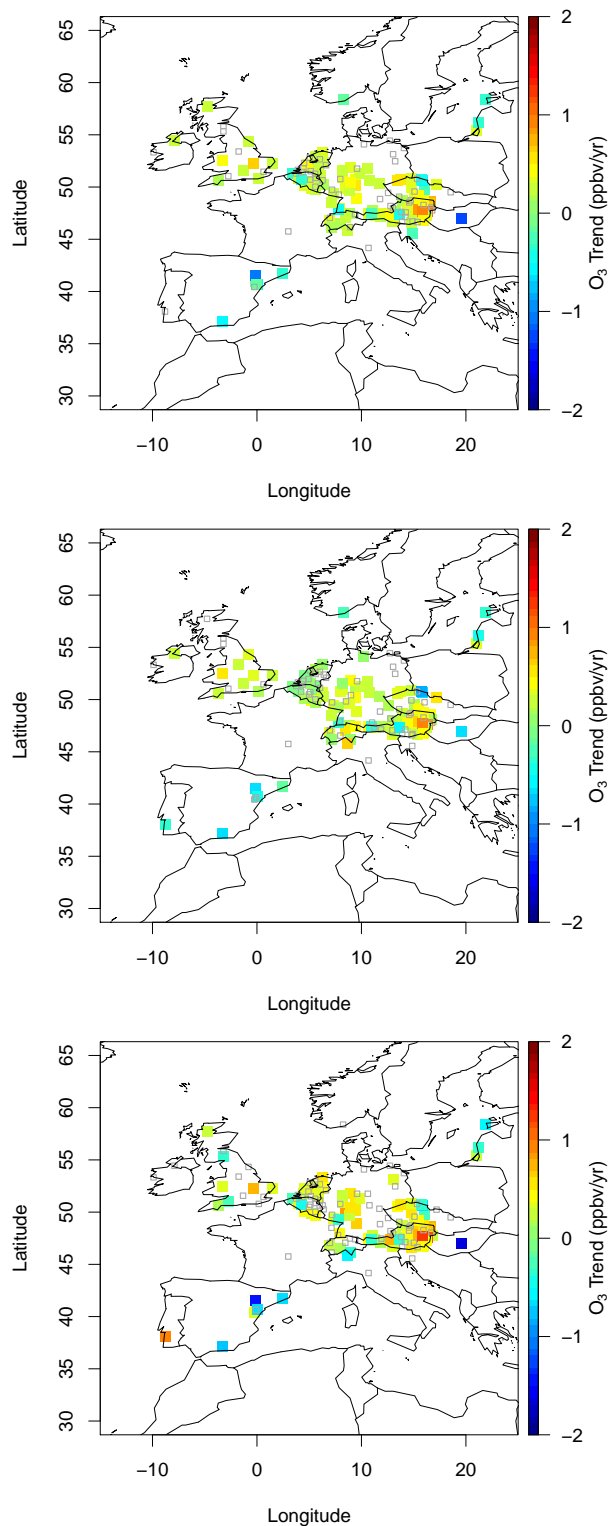

Fig. 5. Spatial distribution of statistically significant annual trends ($p < 0.1$) in observed O_3 mean (top), 5th (middle) and 95th (bottom) percentiles. Open squares represent sites with no statistically significant trends.

Table 2. Manual categorisation of O_3 time series by loess smoothing. NT – no trend, P – positive trend, N – negative trend, I + D increasing then decreasing levels, D + I – decreasing then increasing levels, C – complex behaviour.

(-0.45 to -4.11 % yr^{-1}). The greatest reduction is observed at HU0002R (K-puszt). The linear trends calculated for the remaining 55 sites, located throughout Europe, are not statistically significant ($p > 0.1$). The European-averaged annual trend in mean O_3 is 0.16 ± 0.02 ppbv yr^{-1} (2σ error), with a total range of -1.28 to 1.05 ppbv yr^{-1} .

The low percentiles in an ozone distribution can be representative of the influence of “background” ozone, or be a result from a decreasing trend in removal by reaction with locally emitted NO (for example see Jenkin, 2008). Often these two effects have different seasonal patterns as during winter shallow inversion layers can cause elevated NO_x concentrations, even at rural sites. Previous work (Lindsog et al., 2003) with NO_x integrated trajectories has shown a decrease in the winter ozone deficit across Europe. Examination of O_3 5th percentiles demonstrates that 82 of the 158 sites in central and north-western Europe have significant ($p < 0.1$) positive linear trends. The range across those sites with a positive significant trends was 0.00 to 0.98 ppbv yr^{-1} (0.00 to 20.02 % yr^{-1} , rounded to 2 decimal places) (see Fig. 5 and Table A3 in the Supplement). The highest trends in ozone 5th percentiles are seen in several Austrian sites, with trends of 0.98 ppbv yr^{-1} for AT0154 (Wiesmath) and AT0167 (Payerbach). These findings are similar to the increasing background trends identified in baseline O_3 in north-west European and Alpine regions (including sites in Ireland, Scotland, Norway, Sweden, Finland and high altitude sites) between the early 1990s to early 2000s (Lindsog et al., 2003) and are consistent with observations across the Northern Hemisphere (Carslaw (2005); Vingarzan (2004) and references therein). Similar to the annual mean O_3 trends, the largest

trend of the 5th percentiles, in terms of percentage increase per year, is observed at IT04 (Ispra), which is influenced by the extremely low O₃ levels (<2 ppbv) at the beginning of the measurement period attributed to NO titration in stagnant air masses. Therefore, emission reductions most likely caused this trend.

19 of the 158 sites typically in the outermost locations of Europe, some near-coastal, display significant ($p < 0.1$) negative trends in O₃ 5th percentiles, with a range of -0.03 to -0.88 ppbv yr⁻¹ (-0.67 to -6.32 % yr⁻¹). A total of 57 of the 158 sites have linear trends that are not statistically significant, suggesting that low percentile O₃ may not have substantially changed at these sites between 1996–2005. The European annual trend in O₃ 5th percentiles is 0.13 ± 0.02 ppbv yr⁻¹ (2σ error), with a total range of -0.88 to 0.98 ppbv yr⁻¹.

Figure 5 (compiled from Table A4 within the Supplement) illustrates that significant ($p < 0.1$) 1996–2005 O₃ 95th percentile linear trends are positive across 71 of the 158 sites predominantly in central, north-western and western Europe, with a range of 0.15 to 1.21 ppbv yr⁻¹ (0.24 to 2.16 % yr⁻¹). Peak ozone values and their trends are often taken as evidence for the number and frequency of photochemically induced events (see for example Jenkin, 2008). Just 19 of the 158 sites scattered throughout Europe display negative linear trends ($p < 0.1$), with a range of -0.21 to -1.62 ppbv yr⁻¹ (-0.38 to -3.12 % yr⁻¹), consistent with previous analyses of sites in the United Kingdom, Denmark, Norway, Sweden, Netherlands, Germany, Switzerland and Lithuania which showed a decrease in peak (95th or 98th percentiles) O₃ levels from the early 1990's to early 2000's (Lindskog et al., 2003; Jenkin, 2008; Brönnimann et al., 2002). Furthermore, 68 of the 158 sites throughout Europe display trends that were not statistically significant, suggesting that O₃ levels at these sites may not have substantially altered during the period. The European annual trend in O₃ 95th percentiles is 0.16 ± 0.03 ppbv yr⁻¹ (including 2σ error propagation), with a total range of -1.62 to 1.21 ppbv yr⁻¹. It is interesting to note that these observations on the surface seem to contradict the perceived wisdom that emission reductions across Europe have reduced peak ozone levels.

3.2 Testing the influence of individual years in the annual trend

To establish how the overall annual ozone trend calculated in this study is affected by the data from any given year, the influence of individual years on the the annual trend in the 1996–2005 time period has been investigated. Table 3 summarises the European-averaged trends (using all 158 sites, 2σ error) for O₃ mean, 5th and 95th percentiles when data from one year is systematically excluded. The deviation from the European-averaged annual trends for mean, 5th and 95th percentiles are given in Fig. 6. The removal of individual years 1997, 1998 and 1999 from the trend analysis result

Fig. 6. The deviation from the 1996–2005 inclusive European-averaged annual trend in mean, 5th and 95th percentiles when individual years are excluded from analysis.

in higher magnitude overall positive trends, with a greater proportion of statistically significant ($p < 0.1$) sites showing positive trends. In contrast, the removal of data from 2003 or 2004 respectively from the trend analysis has a profound influence resulting in negative overall annual trends in O₃ 95th percentiles. A lower number of sites exhibit significant trends, of these a higher proportion of sites exhibit negative annual trends in O₃ mean, 5th and 95th percentiles if 2003 or 2004 are excluded from analysis.

Despite using 10 yr time series for trend analysis, inter-annual and extreme variation of meteorological and climatological conditions can have a strong influence on trends during the selected time period (Jonson et al., 2006). Visual inspection of the O₃ time-series (available in the Supplement in Fig. A1) highlights that many sites exhibit unusually high O₃ levels in 1997–1998 and/or 2003. A number of phenomena occurred during these time periods that could have had a substantial influence on the observed O₃ concentrations. The relatively high O₃ monthly means in 1998/1999 have been linked to large-scale global biomass burning, in conjunction with an El Niño event between 1997–1998 (Simmonds et al., 2004). Similarly, Jaffe et al. (2004) identified that Siberian biomass burning in the summer of 2003 contributed to increases in background O₃ of 5–9 ppbv at ten sites in the northern hemisphere. Additionally, the European heatwave during the summer of 2003 is a contributory factor leading to high O₃ levels that year (Solberg et al., 2008; Lee et al., 2006; Ordóñez et al., 2005). With European summer heat waves recorded more frequently in recent years (i.e. 2003, 2006, 2007 and 2010), these extreme meteorological/climatological conditions will influence O₃ levels and trends during this time period, potentially masking the effect of emissions reductions on the production of secondary pollutants such as O₃ (Solberg et al., 2008).

Table 3. A summary of European-averaged trends (where $N = 158$ sites) in O_3 mean, 5th and 95th percentiles during the period 1996–2005 with the exclusion of data from individual years. $N(+)$ and $N(-)$ the number of sites with significant ($p < 0.1$) positive and negative trends respectively. Bold text highlights those years with high influence on trends during the overall 1996–2005 period, see text for details.

Excluded Year	Trend Mean	N (+)	N (–)	Trend 5th Percentile	N (+)	N (–)	Trend 95th Percentile	N (+)	N (–)
1996	0.14±0.02	64	18	0.08±0.02	56	21	0.18±0.03	65	17
1997	0.27±0.02	104	15	0.24±0.02	104	19	0.36±0.03	101	11
1998	0.31±0.02	109	4	0.26±0.02	104	8	0.36±0.03	96	4
1999	0.26±0.02	107	11	0.20±0.02	97	13	0.30±0.03	95	6
2000	0.19±0.02	86	15	0.16±0.02	84	16	0.21±0.03	68	14
2001	0.14±0.02	67	17	0.12±0.02	72	22	0.13±0.03	51	19
2002	0.09±0.02	53	19	0.08±0.02	62	23	0.05±0.03	34	24
2003	–0.04±0.02	25	28	0.00±0.02	38	33	–0.14±0.03	13	44
2004	0.02±0.02	41	25	0.03±0.02	45	31	–0.07±0.03	23	37
2005	0.20±0.02	91	16	0.16±0.02	82	13	0.19±0.03	16	17
none	0.16±0.02	85	18	0.13±0.02	82	19	0.16±0.03	71	19

It is apparent that 1998 and 2003 are pivotal years during the 1996–2005 O_3 trend analysis period. Furthermore, we show that meteorological events in a single month (i.e. August 2003 heatwave) can be sufficient to alter the sign of the trend in a ten year time period. Zvyagintsev and Tarasova (2011) similarly identified that changes in relative humidity and in temperature at eight German sites decreased the ozone trends by 0.5–1.0 ppb per 10 yr in the time periods analysed (11 to 16 yr), with a significant proportion of O_3 trends (up to several tens of percent) attributed to trends of these meteorological variables. Investigating trends in significantly longer time-series would be required to limit the effects of such years containing unusually high O_3 levels as a result of extreme meteorological/climatological conditions. Weatherhead et al. (1998) calculate that 30–35 yr of monthly mean data is required to detect a trend of 5 % per decade (0.25 ppbv yr^{–1}) at a 95 % confidence level for a species such as tropospheric O_3 . There are only a limited number of European measuring sites with long O_3 time-series of 20 yr or more, these are presently not temporally harmonised to offer spatial coverage across Europe. It is necessary that the monitoring of trace gas measurements across Europe is continued in order to provide the lengthy time-series required for future trace gas trend analysis on a regional scale, without the masking by meteorological and background ozone variabilities.

Statistical approaches to account for the effects of meteorological variables on tropospheric O_3 trends has been discussed extensively in Thompson et al. (2001). More recently, the approach of using a generalised additive model (Stephan Henne, personal communication) or a generalised linear mixed model (Chan, 2009) to remove part of O_3 variability that can be explained by meteorology provides a clearer indication of O_3 trends resulting from emission reduction measures.

3.3 The characterisation and quantification of seasonal European ozone trends

In order to further investigate the different contributions to the observed ozone trends, seasonal variations of monthly mean, 5th and 95th percentiles of O_3 for 1996–2005 have been calculated for spring (MAM), summer (JJA), autumn (SON) and winter (DJF). Figure 7 shows typical seasonal cycles for 4 sites (available in full in Fig. A2 within the Supplement). The nature of the shape and form of ozone seasonal cycles has been discussed by Monks (2000). For example, the seasonal cycles in northern, north-western and western European sites (Great Britain, Ireland, Norway and Portugal) display a spring maximum (or summer minimum), with O_3 peaking typically in April or May. There has been much debate as to the controlling features of ozone seasonal cycles (see for example Monks (2000) and references therein) and the relative contributions of in-situ photochemistry, deposition, stratospheric/tropospheric exchange.

In the case of O_3 5th percentiles, sites in peripheral Europe display a spring time maximum, whilst those in more central locations exhibit either a secondary summer maximum or a broad spring-summer maximum. GB0006R (Lough Navar) and IE31 (Mace Head) display spring maxima in O_3 95th percentiles, consistent with the influence of marine air received at these sites, which is not strongly affected by locally emitted human induced O_3 precursors. The same sort of feature in baseline ozone has been observed in continental Canada (Chan and Vet, 2010). All other sites display either a secondary summer maximum or a broad spring-summer maximum in the 95th percentiles.

Relatively few sites display statistically significant ($p < 0.1$) linear trends in Winter (19 sites), spring (31 sites), summer (30 sites) or Autumn (10 sites) mean O_3 . Of those that are statistically significant, many show positive trends

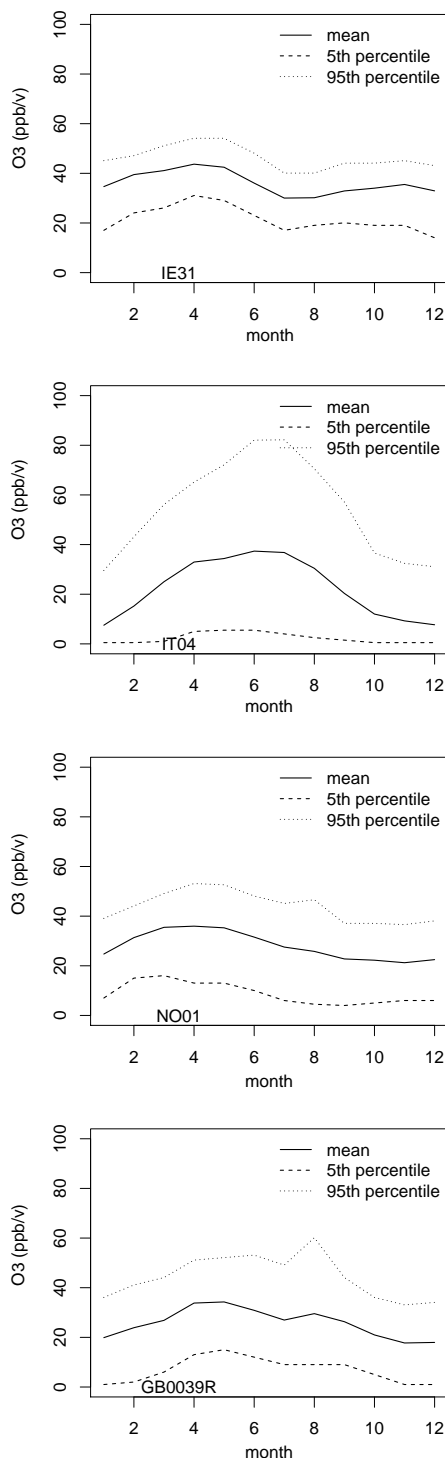

Fig. 7. Examples of seasonal cycles from IE31 [Mace Head], IT04 [Ispira], NO01 [Birkenes] and GB0039R [Sibton] showing from top to bottom examples of a spring maximum, broad spring–summer maximum, spring maximum with secondary summer maximum in 95th percentile and a spring and summer maxima in mean, 5th and 95th percentiles. All sites are available in Fig. A2 of the Supplement.

in winter (17 sites), spring (27 sites) and summer (23 sites) (0.3 to 1.31 ppbv yr⁻¹, 0.28 to 1.65 ppbv yr⁻¹ and 0.37 to 1.15 ppbv yr⁻¹, respectively). Additionally, there are negative trends at a small number of sites in winter (ES1437A and ZUG), spring (EE0011R, HU0002R and NO01), summer (CZ0001R, DE0009R, DE0684A, DE0754A, HU0002R and LV0010R) and autumn (BE0033R, HU0002R, LV0010R, SI0008R and ZUG) of -0.4 to -0.72 ppbv yr⁻¹, -0.15 to -1.88 ppbv yr⁻¹, -0.40 to -1.27 ppbv yr⁻¹ and -0.46 to -1.60 ppbv yr⁻¹, respectively.

A greater number of sites display statistically significant ($p < 0.1$) linear trends of O₃ 5th percentiles in winter (43 sites), spring (34 sites), summer (44 sites) or autumn (26 sites) than for the respective seasonal mean O₃. Of these sites, many show positive trends in winter (33 sites), spring (29 sites) and summer (33 sites) (0.09 to 1.30 ppbv yr⁻¹, 0.06 to 1.65 ppbv yr⁻¹ and 0.04 to 1.15 ppbv yr⁻¹, respectively). Negative trends are observed at a number of sites in winter (10 sites, 6 of which are in Spain), spring (5 sites), summer (11 sites) and autumn (19 sites) with a range of -0.12 to -1.01 ppbv yr⁻¹, -0.02 to -1.88 ppbv yr⁻¹, -0.20 to -1.27 ppbv yr⁻¹ and -0.08 to -1.60 ppbv yr⁻¹ respectively. The seasonal linear trends in O₃ 5th percentiles tend to be of the greatest magnitude during winter and spring, suggesting these have the most influence on the typically increasing annual trends in 5th percentiles of O₃.

Very few sites display statistically significant ($p < 0.1$) linear trends of O₃ 95th percentiles in winter (18 sites), spring (19 sites), summer (28 sites) or autumn (11 sites) (available in full in Table A7 in Supplement). Of these, many show positive trends in winter (15 sites), spring (18 sites) and summer (18 sites) (0.25 to 1.30 ppbv yr⁻¹, 0.24 to 1.65 ppbv yr⁻¹ and 0.26 to 1.15 ppbv yr⁻¹, respectively), with the highest magnitude often exhibited in summer at a time of maximum photochemistry, consequently having the largest influence on annual trends in 95th percentiles of O₃. Negative trends are observed at a number of sites in winter (3 sites), spring (2 sites), summer (10 sites) and particularly autumn (10 sites) with values of -0.41 to -0.70 ppbv yr⁻¹, -1.22 to -1.88 ppbv yr⁻¹, -0.07 to -1.30 ppbv yr⁻¹ and -0.37 to -2.94 ppbv yr⁻¹ respectively.

An average European seasonal cycle 1996–2005 (inclusive), calculated using all sites from this study shows a broad spring–summer maximum in mean O₃ (Fig. 8), with a secondary summer maximum. This summer maximum is most dominant in the O₃ 95th percentile seasonal cycle, peaking in August when there is increased photochemical activity. The European averages of both seasonal and annual trends have been calculated and included on Fig. 8 using the data from all 158 sites. Averaged across Europe, trends in O₃ 5th and 95th percentiles are positive during winter, spring and summer. The greatest magnitudes are observed in winter 5th (0.26 ± 0.07 ppbv yr⁻¹, 2σ error) and spring for both O₃ 5th and 95th percentiles, with values of 0.24 ± 0.05 ppbv yr⁻¹ and 0.31 ± 0.09 ppbv yr⁻¹ respectively. Autumn trends in

Fig. 8. The average European seasonal O₃ cycle for mean, 5th and 95th percentiles. Annotations display the statistically significant ($p < 0.1$) European-averaged seasonal (winter, spring, summer, autumn) and annual trends in ppbv yr⁻¹ (2σ errors).

both 5th and 95th percentiles are negative with values of -0.05 ± 0.05 ppbv yr⁻¹ and -0.20 ± 0.09 ppbv yr⁻¹ respectively.

4 Trends in emissions as represented in inventories

In order to explore the factors driving the observed ozone trends, the trends in the corresponding emission inventories for the anthropogenic ozone precursors have been examined. Trend analysis of EMEP anthropogenic NO_x and VOC emissions (Vestreng et al., 2006) (available at <http://www.ceip.at/>) for Europe during the observation period 1996–2005 are shown in Fig. 9. For scaling purposes, only statistically significant ($p < 0.1$) trends between -10 to 10 % yr⁻¹ are displayed on the maps. In the emission inventory data the majority of Europe show negative trends in excess of -3.00 % yr⁻¹ in NO_x and VOC emissions, consistent with NO_x emissions trends calculated for 1996–2005 by Konovalov et al. (2008) who determined reductions of -4.7 ± 0.6 % yr⁻¹, -3.7 ± 0.7 % yr⁻¹ and -2.8 ± 1.3 % yr⁻¹ for Great Britain, Germany and France respectively. These reductions are thought to be influenced by the introduction of European legislation and the mandatory use of catalytic converters in vehicles (Monks et al., 2009; Vestreng et al., 2009). Spain and Portugal display positive trends in NO_x, with the Iberian and Italian coasts highlighting high positive NO_x trends of up to 10.00 % yr⁻¹ ($p < 0.1$). These coastal regions are affected by the Atlantic and Mediterranean shipping tracks (Konovalov et al., 2008). Positive NO_x trends are also noted in Austria and Hungary which may be linked to the economic recovery of Eastern European countries since the late 1990's (Vestreng et al., 2009). VOC emissions across

Fig. 9. Spatial distribution of significant ($p < 0.1$) annual trends (between -10 to 10 % yr⁻¹) in NO_x (top), VOCs (middle) (both from the EMEP emission inventory, see text for details) and mean O₃ (bottom) 1996–2005 inclusive. Open squares = sites with no statistically significant trends, black lined squares are O₃ surface data 1995–2003 included from Sicard et al. (2009).

Fig. 10. Correlation of statistically significant annual trends in NO_x (from the EMEP emission inventory, see text for details) and observed O_3 (40 sites).

Europe have decreased with the exception of North Sea fossil fuel sites and the Iberian peninsula.

Trends in O_3 ($\% \text{ yr}^{-1}$) are also given in Fig. 9, including those from French sites between 1995–2003 (Sicard et al., 2009), which are consistent with trends from sites within this study. Comparing observed O_3 and anthropogenic emissions, the Austrian sites show a record of positive trends in NO_x and observed O_3 trends in addition to negative trends in VOC emissions between 1996–2005 (Fig. 9). In contrast, Spanish sites display positive trends in NO_x , whilst negative trends in VOCs and observed O_3 . Anthropogenic NO_x (see Fig. 10) and VOC reductions appear to be uncorrelated to O_3 annual trends in the rest of Europe (Fig. 9), suggesting precursor emissions may not have as directly related an effect on O_3 formation at these sites. Consideration must also be given to meteorological conditions, chemical reactions (e.g. NO_x titration) and the trans-boundary transport of ozone and its precursors to the measurement sites.

5 A comparison with a regional chemical transport model

In order to investigate the impact of emission reductions on a regional scale for comparison to observed measurements, simulated O_3 from the CHIMERE chemical transport model was analysed. CHIMERE (Schmidt et al., 2001) was used to generate simulated O_3 concentrations for a regional domain including Europe, with a horizontal resolution of $1^\circ \times 1^\circ$. The boundary conditions used are monthly varying climatologies calculated by averaging multi-year simulation (1999–2005) of the LMDZ-INCA climate-chemistry model. Therefore the boundary conditions reflect an annual cycle of background pollutants. In this work, the model considers only the evolution of meteorological conditions and emissions. The bound-

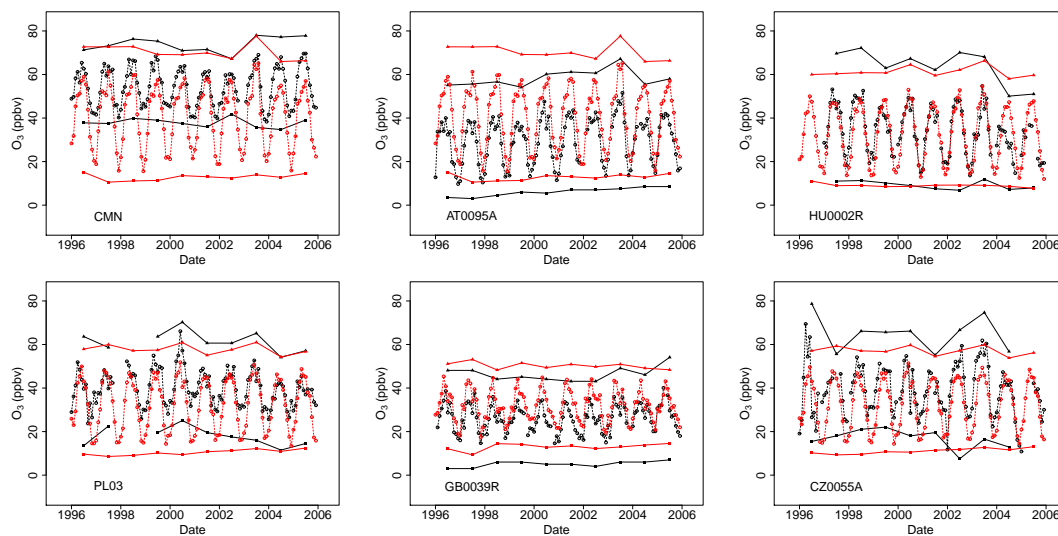

ary conditions do not account for the year to year variability nor for global trends. However, as shown by Vautard et al. (2006), an imposed trend in boundary conditions does not improve the skills of CHIMERE to reproduce the observed trends. For these reasons and because there was no global climatology consistent and continuous over the 1990–2008 time period available at the time we did this simulation, we do not consider the long-term boundary condition variations. Emission inventories were taken from EMEP (Vestreng et al., 2006) (see Sect. 4 for details of trends in this emission inventory). Hourly concentrations of O_3 of each year 1996–2005 (inclusive) were extracted from grid squares closest to the site locations given in Table C1 of the Supplement and assigned to these sites.

Loess regression and linear regression (available in full in Appendix B Fig. B1 and Tables B1–B3 of the Supplement) of annual mean, 5th and 95th percentiles have characterised and quantified trends in CHIMERE simulated O_3 with data extracted for the 158 locations of measurement sites used in this study. Figure 11 gives examples of the CHIMERE monthly means from six sites, with the corresponding observed sites from Fig. 4. From a visual inspection, CHIMERE time-series are of the similar magnitude and variability as the observed O_3 time-series, with the exception of some high altitude sites. As CHIMERE O_3 concentrations were extracted from the surface layer of the model, this may explain the differences between the minimum O_3 levels in the model and observed time-series (Fig. 11) as a result of surface deposition in the model, but not at the elevated site. These six sites were representative of different loess trends categorised manually from a visual inspection of the observed data (Fig. 4). However, the loess trends of the CHIMERE monthly mean O_3 from equivalent sites are more static, showing no apparent trend.

Despite the limited sites with statistically significant trends ($p < 0.1$), annual trends in mean O_3 tend to be positive with a range of 0.09 to 0.32 ppbv yr^{-1} (37 sites) with just 5 sites displaying a negative trend with a range of -0.08 to $-0.14 \text{ ppbv yr}^{-1}$ (Fig. 12). Similarly, significant ($p < 0.01$) trends in annual 5th percentiles of O_3 are also positive, with a range of 0.09 to 0.56 ppbv yr^{-1} (74 sites). Annual trends ($p < 0.01$) in 95th percentiles of O_3 tend to be negative with a range of -0.11 to $-0.46 \text{ ppbv yr}^{-1}$ (20 sites). Comparing significant annual mean and 5th percentile trends in simulated and observed O_3 , the trends in simulated O_3 lie within the broad range of observed trends. In the case of significant ($p < 0.1$) annual trends in 95th percentiles, contrary to the negative trends quantified from CHIMERE output, observed trends at almost half of the sites (71 sites) are positive. Inspection of the monthly mean O_3 levels from the observed and simulated sites (Fig. 13), show that the CHIMERE model configuration slightly underestimates the mean O_3 in winter and greatly over estimates the mean O_3 levels from May to August, leading to differences between daily observed and simulated O_3 annual trends in mean, 5th and 95th percentiles.

Table 4. Summary of the average European annual trends (ppbv yr^{-1} , with 2σ error) from observations at all 158 sites in Fig. 1 and the CHIMERE simulation.

Source	Period	Mean (ppbv yr^{-1})	5th Percentile (ppbv yr^{-1})	95th Percentile (ppbv yr^{-1})
Observations – annual trend	1996–2005	0.16 ± 0.02	0.13 ± 0.02	0.16 ± 0.03
CHIMERE – annual trend	1996–2005	0.05 ± 0.01	0.13 ± 0.01	-0.03 ± 0.02

**Fig. 11.** Examples of loess trends of observed (black) and CHIMERE simulated (red) monthly mean O_3 (ppbv yr^{-1}) (Full details of observed sites given in Fig. A1 of the Supplement, full CHIMERE simulated sites given in Appendix B Fig. B1 of the Supplement). Circles = monthly mean, squares = annual 5th percentile, triangle = annual 95th percentile.

Frequency distributions of the observed and CHIMERE modelled annual O_3 trends in mean, 5th and 95th percentiles are given in Fig. 14 for (i) all trends and (ii) only those that are statistically significant ($p < 0.1$). It is clear that whilst the range of O_3 annual trends is the same when looking at only statistically significant trends or all trends, the distribution of trends is different. In the observed trends the distribution is unimodal for O_3 mean, 5th and 95th percentiles when accounting for all annual trends (with frequencies peaking at 0.1 to 0.2 ppbv yr^{-1} , 0.0 to 0.1 ppbv yr^{-1} and 0.2 to 0.3 ppbv yr^{-1} respectively). When just statistically significant ($p < 0.1$) trends are taken into account, unimodal distribution of trends is seen for 5th percentiles peaking at 0.2 to 0.3 ppbv yr^{-1} , but bimodal distributions are seen for both mean (with frequency peaking at -0.4 to $-0.3 \text{ ppbv yr}^{-1}$ and 0.2 to 0.3 ppbv yr^{-1}) and 95th percentiles (with frequency peaking at -0.4 to $-0.3 \text{ ppbv yr}^{-1}$ and 0.3 to 0.5 ppbv yr^{-1}).

In comparison, ranges of CHIMERE annual O_3 trends are similar for both mean and 5th percentiles whilst those for 95th percentiles are different. The CHIMERE annual O_3 trends in mean, 5th and 95th percentiles exhibit a unimodal distribution when considering all trends (peaking at 0.0 to 0.1 ppbv yr^{-1} , 0.0 to 0.1 ppbv yr^{-1} and -0.1 to 0.0 ppbv yr^{-1}

respectively). A unimodal distribution of the statistically significant trends of O_3 mean (with frequency peaking at 0.1 to 0.2 ppbv yr^{-1}), 5th (with frequency peaking at 0.1 to 0.2 ppbv yr^{-1}) and 95th (with frequency peaking at -0.2 to $-0.1 \text{ ppbv yr}^{-1}$) percentiles is also observed, in contrast to the bimodal distribution in observed O_3 mean and 95th percentiles. The CHIMERE model distributions for annual trends in O_3 mean, 5th and 95th percentiles tend to have a peak frequency at a lower value than the observed data.

The average European trends for annual mean, 5th and 95th O_3 percentiles have been calculated, with 2σ errors, for all sites observed and those extracted from the CHIMERE regional model (see Table 4). There is good agreement between the observed and CHIMERE European-averaged 5th percentile trends ($0.13 \pm 0.02 \text{ ppbv yr}^{-1}$ and $0.13 \pm 0.01 \text{ ppbv yr}^{-1}$ respectively). However, there is poorer agreement between the observed and the CHIMERE European-average trends in an mean ($0.16 \pm 0.02 \text{ ppbv yr}^{-1}$ and $0.05 \pm 0.01 \text{ ppbv yr}^{-1}$ respectively) and the 95th percentiles ($0.16 \pm 0.03 \text{ ppbv yr}^{-1}$ and $-0.03 \pm 0.02 \text{ ppbv yr}^{-1}$ respectively).

Fig. 12. Spatial distribution of significant ($p < 0.1$) annual CHIMERE modelled trends (ppbv yr^{-1}) in O_3 mean (top), 5th (middle) and 95th percentiles (bottom) 1996–2005. Open squares = sites with no statistically significant trends.

Fig. 13. A comparison of the European average O_3 observed monthly mean and annual 5th and 95th percentiles and the CHIMERE model output for all 158 site locations.

6 Summary and conclusions

The establishment of temporal ozone trends is important for quantifying the impact of changing precursor emissions and also from the perspective of local and regional air quality control in terms of import/export of ozone and the amount that is locally or regionally controllable. Using ozone data from 158 European rural background observation sites over the time period 1996–2005, the annual and seasonal trends have been determined. A paucity of monitoring sites in France, Spain and the Mediterranean area in the harmonised dataset used (owing to not being available through the monitoring networks used) may lead to a bias towards the ozone trends within central/northern Europe. Ozone time-series at each station was manually characterised as having positive, negative, a combination of these increasing and decreasing concentrations, complex behaviour and static forms of temporal evolution.

Annual linear trends were calculated by de-seasonalising the ozone time series and using Mann-Kendall analysis of Sen-Theil slopes. The overall annual European-averaged trend was net positive, $0.16 \pm 0.02 \text{ ppbv yr}^{-1}$ (2σ error). When the European-averaged annual trends are decomposed into percentiles, both the 5th (background) and the 95th percentiles (peak) show positive trends of $0.13 \pm 0.02 \text{ ppbv yr}^{-1}$ and $0.16 \pm 0.03 \text{ ppbv yr}^{-1}$ respectively (2σ error).

Stations in south-western and eastern Europe had negative trends in 5th and 95th percentiles and means, whereas most of the central and north-western stations had positive trends. Assessment of the sensitivity of the derived trends to the years included in the decadal average show that the net positive trend is heavily weighted by the 2003 NW European “heatwave” year while the early part of the chosen

Fig. 14. A comparison of the frequency distribution of annual trends in observed (top) and CHIMERE (bottom) O₃ mean, 5th and 95th percentiles.

decade is heavily influenced by 1997–1998 El Niño/biomass burning years. The dependency on the selection of the years highlights the role of variability driven by chemical and meteorological processes. The observed spatial variability of the trends could reflect the sphere of influence of the 2003 event (Vautard et al., 2005). It is clear that the identified year-by-year variations, caused by meteorological variability could be masking the impact of emission reductions on long-term ozone trends. In order to better assess the influence of emission changes on the observed ozone, alternative statistical approaches are required to remove the influence of the meteorological variability such as using general additive or generalised linear models (e.g. Chan, 2009; Chan and Vet, 2010).

European trends in NO_x and VOC emissions from the EMEP inventory show near uniform decrease in ozone precursor emissions (apart from increases in NO_x in southwestern Europe) across Europe which are not directly reflected in the observed ozone trends.

The average ozone seasonal cycle over Europe (from these 158 stations as shown in Fig. 8) displays a spring maximum for the 5th percentile and both a high spring maximum with a secondary summer maximum for the mean and 95th percentiles. There are positive seasonal ozone trends in spring, summer and autumn in 5th and 95th percentiles. The highest magnitude trend in 5th percentile and mean O₃ are observed in winter (0.26 ± 0.07 ppbv yr⁻¹, 2σ error) and 0.26 ± 0.07 ppbv yr⁻¹ respectively. The highest trend out of all seasons was found in spring 95th percentiles (0.31 ± 0.09 ppbv yr⁻¹) and the summer 95th percentile was also high (0.24 ± 0.10 ppbv yr⁻¹) and these periods of high

photochemical activity would suggest an increase in ozone precursor build up and photolysis over the years. Mean, 5th and 95th percentile autumn ozone trends are negative, with the greatest negative magnitude observed in the 95th percentile (-0.20 ± 0.09 ppbv yr⁻¹).

Simulated ozone was extracted at the coordinates of the 158 measurement stations from the CHIMERE regional chemistry transport model. The CHIMERE model displays small positive annual trends in European-averaged mean ozone (0.05 ± 0.01 ppbv yr⁻¹) and 5th percentiles (0.13 ± 0.01 ppbv yr⁻¹), with annual trends in 5th percentiles closely matching that of European-average observed trends. It is noted that CHIMERE tends to overestimate the ozone levels in summer months relative to observed ozone, consequently CHIMERE European-averaged trends in 95th percentiles (-0.03 ± 0.02 ppbv yr⁻¹, 2σ error) do not match those in observed ozone (0.16 ± 0.03 ppbv yr⁻¹). Expanded analysis of the CHIMERE model output and its validation against alternative (e.g. MOZAIK) or a limited number of longer datasets is required to investigate and understand the observed trends.

The ensemble approach of using many regional background sites does seem a robust way of exploring regional ozone trends. The ability to use distribution statistics on these ensembles as a way of challenging models needs to be explored further.
