Abstract. New particle formation (NPF) is considered as an important mechanism for gas-to-particle transformation, and gaseous sulfuric acid is believed as a crucial precursor. Up to now few field-based studies on nucleation mechanisms and the role of sulfuric acid were conducted in China. In this study, simultaneously measurements of particle number size distributions and gaseous sulfuric acid concentrations were performed from July to September in 2008. Totally, 22 new particle formation events were observed during the entire 85 campaign days. The results show that in the case of both higher source and sink values, the result of the competition between source and sink is more likely the key limiting factor to determine the observation of NPF events in Beijing. The concentrations of gaseous sulfuric acid show good correlations with freshly nucleated particles ($N_{3-6}$) and formation rates ($J_3$ and $J_{1.5}$). The power-law relationship between $H_2SO_4$ concentration and $N_{3-6}$ or $J$ is adopted to explore the nucleation mechanism. The exponents were showed a great range (from 1 to 7). More than half of the NPF events exhibit an exponent larger than 2.5. For these cases, the thermo-dynamic process works better than the activation or kinetic nucleation theories to explain the nucleation events in urban atmosphere of Beijing.

1 Introduction

New particle formation (NPF) and the subsequent particle growth have been observed in various environments all over the world (Kulmala et al., 2004; Holmes, 2007). Model results suggest that nucleation may be an important source of condensation nucleus (CN) and cloud condensation nuclei (CCN) in global scale (Spracklen et al., 2008; Merikanto et al., 2009). The particle growth could affect the global climate system by scattering and absorption of solar radiation directly (Stier et al., 2007). Furthermore, these particles may act as CCN and ice nuclei (IN) and influence the climate system indirectly (Lohmann and Feichter, 2005). In order to obtain an improved understanding of the various effects of atmospheric particles, the properties of the nucleation and growth should be understood completely and validated for different areas.

Gaseous sulfuric acid has been identified as a key component in the NPF process (Weber et al., 1995; Kulmala, 2003; Berndt et al., 2005; Fiedler et al., 2005) and proposed as a key component in many nucleation theories, such as binary, ternary or ion-induced nucleation (Korhonen et al., 1999; Weber et al., 1999; Yu and Turco, 2000; Napari et al., 2002; Vehkamaki et al., 2002). In order to investigate the role of sulfuric acid in the nucleation process, based on recent observations the relationship between observed nucleation rates and ambient gaseous sulfuric acid concentrations with an exponent between 1 ($J$=A $\times$ [H$_2SO_4$]) and 2 ($J$=K $\times$ [H$_2SO_4$]$^2$) have been reported (Sihto et al., 2006; Riipinen et al., 2007; Boy et al., 2008; Kuang et al., 2008; Nieminen et al., 2009; Paasonen et al., 2009). In these

Correspondence to: M. Hu
(minhu@pku.edu.cn)
publications the authors pointed out that the activation and kinetic nucleation maybe the potential formation mechanisms. Meanwhile, the role of low-volatile organic vapors to atmospheric nucleation caused widespread attentions and several recent studies suggested that organic vapors do participate in the nucleation process (Bonn et al., 2008; Paasonen et al., 2009, 2010; Lauros et al., 2011).

Although the NPF events were observed all over the world, the measurements of gaseous sulfuric acid are rare, especially in urban polluted environment. A few campaigns had been conducted in urban environments only provide the measurements of particle number size distributions (Dunn et al., 2004; Kulmala et al., 2005; Hamed et al., 2007; Smith et al., 2008; Salma et al., 2011). High frequency of NPF event was observed in Beijing based on a one-year statistical analysis (Wu et al., 2007). Yue et al. (2010) pointed out that sulfuric acid plays a dominant role in both the nucleation and subsequent growth processes. Nevertheless, the relationship between sulfuric acid and freshly nucleated particles or formation rates is still unclear.

In this paper, we present the Beijing case for the NPF as an urban polluted atmosphere. Based on simultaneous measurements of particle number size distributions and gaseous sulfuric acid concentrations, the role of sulfuric acid to NPF is explored in order to answer the following questions: (1) what is the limiting factor to determine the occurrence of the NPF events in Beijing, (2) how do the freshly nucleated particles and nucleation rates depend on the sulfuric acid concentrations, and (3) how do the activation and kinetic nucleation theories apply in the urban environment and what are the differences compared with other atmospheric environments.

2 Materials and methods

2.1 Measurements

The measurements were conducted at an urban site, the campus of Peking University (39.99° N, 116.31° E). The observatory is located on the sixth floor of an academic building (about 20 m above the ground level). Detailed descriptions of the measurement site and surrounding environment can be found in Wu et al. (2008). Both particle number size distributions and sulfuric acid measurements were carried out from 12 July to 25 of September, 2008.

Number size distributions of atmospheric particles from 3 to 900 nm (mobility diameter) were measured by a TDMPS (Twin Differential Mobility Particle Sizer) system with 10 min time resolution. It consists of two parallel differential mobility analyzers (DMAs) that classify particles in the size ranges 3–80 nm and 40–900 nm. The relative humidity within the whole system was kept below 30%. The TDMPS system was described in more detail by Wehner et al. (2008).

The gaseous sulfuric acid concentration was measured by an AP-ID-CIMS, which was developed at Texas A&M University. The time resolution was 12 s, and then the data were averaged to 10 min in order to reduce statistical error and keep consistent with the particle number size distribution. Detailed descriptions of the instrument and the measurement of gaseous sulfuric acid in the same campaign were introduced by Zheng et al. (2011).

2.2 Data analysis

2.2.1 Time delay $\Delta t$ and growth rate $GR$

Recent observations and laboratory calculations imply the diameter of the nucleation particles is around 1.5 nm (Kulmala et al., 2007; Zhang, 2010). The lowest detecting diameter measured by the TDMPS is however 3 nm. Freshly nucleated particles are thus not observed at the same time of their formation but after a time interval $\Delta t$, until they grow up to the diameter of 3 nm. This time delay implies that the increase in the concentration of small particles is preceded by the increase in sulfuric acid concentration. Based on this assumption, the growth rate from the nucleation size (1.5 nm in this study) to the detectable size (3 nm) can be expressed as:

$$GR_{1.5 \rightarrow 3} = \frac{3 \text{ nm} - 1.5 \text{ nm}}{\Delta t} = \frac{1.5 \text{ nm}}{\Delta t}$$

where $\Delta t$ is defined as the time delay between the sulfuric acid concentration and $N_{3,6}$, where $N_{3,6}$ refers to the particle number concentration in the size range 3–6 nm (covers the five lowest channels of the TDMPS) which could considered as the freshly nucleated particles to a great extent.

However the model simulation results indicate that the time delay method has its limitation, especially in the case of strong particle formation events (Korhonen et al., 2011). The previous formed nucleation mode particles could act as an extra coagulation sink for the small clusters that form later, which may cause the peak of $N_{3,6}$ arised earlier than in the case of purely condensation controlled formation of these small particles. As a result, the time delay between $N_{3,6}$ and sulfuric acid concentration may equal to zero or even negative in these cases. Another possible explanation for the case of no time delay observed is that the rapid growth from nucleation size to detectable size and limitation of instrument (TDMPS) time response. We assume that it may take 10 min (time resolution of instruments) for particles to grow up from 1.5 nm to 3 nm pointing to $GR_{1.5 \rightarrow 3}$ equal to 9 nm h$^{-1}$ (which is $3 \rightarrow 1.5$) nm 10 min). In these cases, the real growth rate should be larger than 9 nm h$^{-1}$.

2.2.2 Particle formation rates $J_3$ and $J_{1.5}$

The time evolution of $N_{3,6}$ is described with a balance equation:

$$\frac{dN_{3,6}}{dt} = GR_3 \cdot n_3 - GR_6 \cdot n_6 - CoagS_{3,6} \cdot N_{3,6}$$

where $n$ is the particle size distribution function, defined as $n_d = dN_d/dp$ with the particle diameter $dp$ and $GR_{dp}$ is the
growth rate of the particles with diameter $d_p$. The CoagS$_{3\rightarrow 6}$ denotes the average coagulation sink for the 3–6 nm range (Kulmala et al., 2001). Hence, this formula includes terms for the growth into the 3–6 nm range over the 3 nm limit (first term), out of the range over the 6 nm limit (second term) and the loss by coagulation scavenging (third term).

By rearranging the terms, and denoting the first term on the right hand side of Eq. (2) by $J_1$, the previous studies (Sihto et al., 2006; Paasonen et al., 2009) gave the Eq. (3) to calculate the particle formation rate at 3 nm:

$$J_3 = \frac{dN_{3\rightarrow 6}}{dt} + \text{CoagS}_4 \cdot N_{3\rightarrow 6} + \frac{1}{3} \text{GR}_6 \cdot N_{3\rightarrow 6}$$

(3)

The approximations made in Eq. (3) are the following: (1) the CoagS$_{3\rightarrow 6}$ has been approximated by a term representing the loss of 4 nm sized particles (4 nm is approximately the geometric mean of 3 and 6 nm) and CoagS$_4$ could be calculated directly from the measured particle number size distribution, (2) the condensation loss out of the size range 3–6 nm is obtained by approximating $N_6$ by $N_{3\rightarrow 6}/(6$ nm–3 nm) and the GR$_6$=GR, respectively. Here GR is estimated from the time delay between sulphuric acid and N$_{3\rightarrow 6}$ as shown in the Eq. (1).

However, the recent studies (Vuoellkeski et al., 2010; Korhonen et al., 2011) show that there are potential problems in determining GR$_{1,5}$. To improve the accuracy of $J_3$ calculation the recommended Eq. (4) is used to simulate the $J_3$ value in this study:

$$J_3 = \frac{dN_{3\rightarrow 6}}{dt} + \text{CoagS}_4 \cdot N_{3\rightarrow 6} + \frac{1}{2} \text{GR}_6 \cdot N_{5\rightarrow 7}$$

(4)

The first and second terms on the right hand side of Eq. (4) are the same as Eq. (3). The differences between these two equations are: (1) here $N_6$ is assumed roughly equal to $N_{5\rightarrow 7}/(7$ nm–5 nm) and (2) the GR$_6$ is assumed closer to the growth rate of the nucleation mode (GR$_{1,5}$ estimated from particle number size distribution in this study) than GR$_{1,5}$.

Based on the $J_3$ values, the nucleation rate $J_{1,5}$ can be estimated using the method presented by Kerminen and Kulmala (2002):

$$J_{1,5}(t) = J_3(t)\exp\left(\gamma \frac{CS'}{GR} \left(\frac{1}{1.5 \text{ nm}} - \frac{1}{3 \text{ nm}}\right)\right)$$

(5)

here $\gamma$ is a coefficient with the approximate value of 0.23 m$^2$ nm$^2$ h$^{-1}$ and $CS'$ is the condensation sink in unit m$^{-2}$. For the condensation sink $CS'$ we use the median value from the interval $[t, t+\Delta t]$.

However, the simulation of nucleation rate $J_{1,5}$ based on the Eq. (5) has great uncertainty. First the assumption of the constant growth rate in Eq. (5) is suspectable (Korhonen et al., 2011). The combined effect of various precursors could cause a strong deviation from the constant growth rate assumption. Second neglecting the intramodal coagulation in the nucleation mode in Eq. (5) may lead in theory to underestimation of $J_{1,5}$. Third the time shift between the $N_{3\rightarrow 6}$ and sulfuric acid concentration was not observed in most cases of this study. In these cases we have to assume the GR is equal to 9 nm h$^{-1}$ (see Sect. 2.2.1), which may overestimate the real nucleation rate.

### 2.2.3 Determination of the nucleation coefficients $A$ and $K$

In this work, we study two nucleation theories using $J_{1,5}$ estimated from the particle measurement data, the activation theory and the kinetic theory (Kulmala et al., 2006). These theories assume that the nucleation rate should have a power law dependence on the sulfuric acid concentration. In the activation theory, the clusters containing one sulfuric acid molecule will activate for further growth due to heterogeneous nucleation, thus the nucleation rate is directly proportional to the sulfuric acid concentration:

$$J_{1,5} = A[\text{H}_2\text{SO}_4]$$

(6)

where $A$ is the activation coefficient (in unit s$^{-1}$).

The kinetic theory (McMurry and Friedlander, 1979; Lushnikov and Kulmala, 1998) suggests that critical clusters are formed by collisions of two sulfuric acid molecules. According to kinetic gas theory, the collision frequency of two molecules is correlated with the concentration of both molecules. The nucleation rate can thus be written as:

$$J_{1,5} = K[\text{H}_2\text{SO}_4]^2$$

(7)

where $K$ is the kinetic coefficient (in unit cm$^3$ s$^{-1}$).

According to previous studies (Sihto et al., 2006), the relationship between nucleation rate and sulfuric acid concentration is in general within the exponent between 1 and 2 which signifies the reasonability of these two theories. On the other hand, the exponents for $J_{1,5}$ vs. H$_2$SO$_4$ clearly in excess of 2 are also observed in some cases (Riipinen et al., 2007; Kuang et al., 2008), which indicate that the atmospheric nucleation is thermodynamically limited (Kulmala et al., 2006). In these cases, the nucleation theory is defined as:

$$J_{1,5} = T[\text{H}_2\text{SO}_4]^n(n > 2.5)$$

(8)

where $T$ is the thermodynamic coefficient (in unit cm$^{(3n-3)}$ s$^{-1}$).

### 3 Results and discussion

#### 3.1 Comparisons of sulfuric acid concentration and condensation sink between the NPF and non-NPF days

The improved air quality during 2008 Olympic Games (UNEP, 2009) with less pre-existing particles enhances the NPF. The frequency of the NPF event (26 %) is higher than our previous studies in the same period of 2004–2007 (11 %–20 %) (Wu et al., 2007; Yue et al., 2009). In total, 22 NPF
This study compares the mean values of the activation A and kinetic coefficients K for sulfuric acid in different sites and sampling periods. The table below summarizes the data:

events are identified out of 85 days from July to September 2008, in which on 17 NPF events both particle number size distributions and sulfuric acid concentrations are simultaneously measured. In this paper, freshly nucleated particles in the size range from 3 to 6 nm are chosen to examine its connection with sulfuric acid concentration. Figure 1 displays the temporal variations of the sulfuric acid ($\text{H}_2\text{SO}_4$), condensation sink (CS) and 3–6 nm particle number concentrations ($N_{3-6}$) for the whole measurement period. It is evident that both the $N_{3-6}$ and $\text{H}_2\text{SO}_4$ have the strong diurnal variations on NPF days (gray background). During some non-event days however, even the $\text{H}_2\text{SO}_4$ concentration goes up to equal levels compared to the event days (e.g. 17 August, day 230 and 2 September, day 247). On these days, an increase in nucleation mode particles with the $\text{H}_2\text{SO}_4$ concentration is not observed. This phenomenon may be due to the high concentration of pre-existing particles, which is also visible in the large CS values. The pre-existing particles could act as a sink to capture for both, condensing vapors and newly formed particles, which could prevent the occurrence of NPF events.

Figure 2a shows the comparison between sulfuric acid concentrations and condensation sink values of NPF-event and non-event days before the nucleation events start (8:00–11:00). It can be seen clearly that on average, the event days are associated with lower condensation sinks than the non-event days. The mean CS (during 8:00–11:00) on NPF event days (0.022 s$^{-1}$) is typically significantly lower than on non-event days (0.045 s$^{-1}$). Even though during NPF event days, the CS value are higher than other observations in clean environments (Riipinen et al., 2007; Boy et al., 2008) or polluted regions (Kulmala et al., 2005; Hamed et al., 2007).
Fig. 3. An example of new particle formation day on 15 August 2008 (day 228) in Beijing. (a) Particle number size distribution, (b) the number concentration of 3–6 nm particles (red) and the sulfuric acid concentration (blue), (c) the number concentration of 3–6 nm particles and the sulfuric acid concentration delayed by the time shift ($\Delta t = 0$ h) and raised to the fitted power ($n = 1.6$) with the best correlation ($R = 0.90$).

In addition, the abundant SO$_2$ concentrations and the high oxidation capacity in the polluted urban environment of Beijing indicates the sufficient source of sulfuric acid (Wu et al., 2007; Yue et al., 2010). The higher number concentration of newly formed particles is observed when the ratio of sulfuric acid concentration to condensation sink is larger, which is shown in Fig. 2b. The NPF event is the product of the competition between source (here represented as sulfuric acid concentration) and sink (CS). In the case of both higher source and sink values, the result of the competition between source and sink is more likely the key limiting factor to determine the observation of NPF events in the urban of Beijing.

3.2 Correlation between freshly nucleated particles and sulfuric acid concentration

The concentrations of newly formed particles and sulfuric acid are obviously correlated on the 17 NPF event days. Figures 3a and 4a show two typical cases of the NPF events observed on 15 August (day 228) and 12 September (day 256), respectively. In both cases a significant nucleation mode is formed around 10:00 and followed by particle growth until the next day. The condensational sink of pre-existing particles before the nucleation event on 15 August (CS = 0.014 s$^{-1}$) is lower than that on 12 September (CS = 0.038 s$^{-1}$). The initial concentration of pre-existing particles may affect the nucleation process and will be discussed later.

Figures 3b and 4b display the diurnal variations of $N_{3−6}$ and sulfuric acid concentrations in two cases, respectively. Unlike other studies (Riipinen et al., 2007; Kuang et al., 2008; Paasonen et al., 2009), the time shift between the rise of $N_{3−6}$ and sulfuric acid concentrations in both cases is not observed. Besides the potential problem in Eq. (1), the rapid growth from cluster size to detectable size may also cause this issue as discussed before. The growth rate in the size range from 3 to 10 nm are 20.1 nm h$^{-1}$ (15 August) and 36.1 nm h$^{-1}$ (12 September), respectively. The best correlations are 0.90 on 15 August with the exponent 1.6 and 0.94 on 12 September with the exponent 6.5, respectively (see Figs. 3c and 4c).

In order to compare our results with the other studies, we choose the same classification as described in Riipinen et al. (2007). The statistic results are shown in Table 1. The mean value of the correlation coefficient is 0.86 ($R$ in the range 0.67–0.96) which reflects a good correlation between $N_{3−6}$ and sulfuric acid. Different from the other studies, with exponents between 1 and 2, the NPF event days of this study, lead to exponents more concentrated between 2.5 and 7 (58 % in 17 investigated days). In addition, we find the exponents of sulfuric acid increase with the CS values in these four categories of Beijing. The mean CS values (8:00–11:00 during nucleation days) are 0.008 s$^{-1}$ ($n ∼ 1$), 0.012 s$^{-1}$ ($n ∼ 1.5$), 0.019 s$^{-1}$ ($n ∼ 2$) and 0.024 s$^{-1}$ ($n > 2.5$), respectively. The exponent in the correlation of $N_{3−6}$ and sulfuric acid concentrations might be related to the background particle concentration and atmosphere nucleation precursors. Therefore, more information on the nucleation process and chemical composition of freshly formed particles is needed.
Table 1. Comparisons of the exponent in the correlation of $N_{3−6}$ and sulfuric acid concentrations with other studies. $R$ refers to the correlation coefficient, $N$ is the number of nucleation event and the value in bracket indicates the percentage accounting for.

3.3 Correlation between particle formation rates and sulfuric acid concentration

The formation rates are calculated based on the particle number size distributions using Eq. (4). Figure 5 shows the diurnal variations of $J_3$ values and sulfuric acid concentrations during the two selected days. A good correlation is observed between $J_3$ and sulfuric acid and for the $N_{3−6}$ and sulfuric acid.

The formation rates $J_3$ and $J_{1.5}$ are plotted versus the sulfuric acid concentrations in Fig. 6. It is obviously that the exponents in the relationships between particle formation rates (both $J_3$ and $J_{1.5}$) and sulfuric acid concentrations are mostly between 1 and 7 in Beijing. It is hard to distinguish the dominant nucleation theories depend on the scatter data plots. The average slopes for the 17 days data set are 2.3 ($J_3$) and 2.7 ($J_{1.5}$), respectively. These values are higher than obtained during the studies in Hyytiälä, Heidelberg or other stations, where the exponents are always between 1 and 2 (Riipinen et al., 2007; Nieminen et al., 2009; Sipila et al., 2010). These results indicate that in the polluted urban environment of Beijing, the thermodynamic process seems involved in the nucleation process, which could not simply explained by activation or kinetic nucleation theory as previous studies.

3.4 Nucleation coefficients

Two cases of the NPF events are observed in Beijing, as mentioned above: (1) the exponent in the correlation of the formation rate and sulfuric acid between 1 and 2, which implies that activation or kinetic nucleation is the possible main nucleation mechanism; (2) the exponent larger than 2.5 indicates that thermodynamic nucleation is the dominate mechanism. The first case is similar with the observations in clean environments (Sihto et al., 2006; Riipinen et al., 2007). In the polluted urban environment of Beijing, more than half of the NPF events (58 %) belong to the second case.

The nucleation activation coefficients $A$ and kinetic coefficient $K$ are calculated by using the Eqs. (1) and (7). The formation rates ($J_{1.5}$) calculated from particle number size distributions and the sulfuric acid concentrations are compared in Fig. 7. It illustrates the correlation between the results from particle size distribution and sulfuric acid measurements on two cases of NPF event days: the exponent between 1 and 2 on 15 August, while greater than 3 on 12 September. On 15 August, the correlation coefficients between activation nucleation and kinetic nucleation are almost the same and the difference is negligible. The kinetic nucleation theory fits better than the activation theory on 12 September. In contrast, the thermodynamic process seems more reasonable than the other two theories (thermodynamic coefficient $T$ are calculated by using the Eq. (8) with the exponent equal to 3).

In order to facilitate comparison with other studies, the nucleation coefficients $A$ and $K$ are calculated for all the

4 Conclusions

This paper focuses on the Beijing case of the NPF in the polluted urban environment. Field-based discussion is made to explore the nucleation mechanism and the role of sulfuric acid. The following conclusions are made.

The mean CS during the time period of 08:00–11:00 on the NPF event days is about half of that in non-event days. The results reveal that in the case of both higher source and sink values, the result of the competition between source and sink is more likely the limiting factors to determine the occurrence of a nucleation event.

Good correlation ($R = 0.86$) between $N_{3-6}$ and sulfuric acid are observed in Beijing. The correlation coefficient values vary from 0.67 to 0.96. Most of the NPF events in Beijing are observed without the time delay between the detection of freshly formed particles and the occurrence of sulfuric acid, which is rarely observed previously. The exponent is larger in other studies, more than half of them are larger than 2.5. Meanwhile, the exponents of sulfuric acid increasing with the CS values are observed in Beijing case.

Formation rates of 3 nm and 1.5 nm particles estimated from particle measurements are correlated with sulfuric acid concentration to the power from 1 to 7 in this study. The mean slopes for the 17 days data set are 2.3 ($J_3$) and 2.7 ($J_{1.5}$), respectively. In more than half of all cases, the thermodynamic process works better than the activation and kinetic nucleation theories, which is different from the previous literatures. The mean values of activation and kinetic coefficients are $1.95 \times 10^{-6} \text{s}^{-1}$ and $3.44 \times 10^{-13} \text{cm}^3\text{s}^{-1}$, respectively. The values of $A$ and $K$ are in the same order as the previous studies.

The larger exponent between particle formation rates and sulfuric acid concentrations implies that besides $\text{H}_2\text{SO}_4$, also other species such as low-volatility organic vapors might be involved in the early stage of NPF events in Beijing. Further investigations on the role of organic compounds in the
initial nucleation process are required and the comparisons with previous studies in other atmosphere environments are very important.
