Abstract. The CANOPEE project aims to better understand the biosphere–atmosphere exchanges of biogenic volatile organic compounds (BVOCs) in the case of Mediterranean ecosystems and the impact of in-canopy processes on the atmospheric chemical composition above the canopy. Based on an intensive field campaign, the objective of our work was to determine the chemical composition of the air inside a canopy as well as the net fluxes of reactive species between the canopy and the boundary layer. Measurements were carried out during spring 2012 at the field site of the Oak Observatory of the Observatoire de Haute Provence (O3HP) located in the southeast of France. The site is a forest ecosystem dominated by downy oak, Quercus pubescens Willd., a typical Mediterranean species which features large isoprene emission rates. Mixing ratios of isoprene, its degradation products methylvinylketone (MVK) and methacrolein (MACR) and several other oxygenated VOC (OxVOC) were measured above the canopy using an online proton transfer reaction mass spectrometer (PTR-MS), and fluxes were calculated by the disjunct eddy covariance approach. The O3HP site was found to be a very significant source of isoprene emissions, with daily maximum ambient concentrations ranging between 2–16 ppbv inside and 2–5 ppbv just above the top of the forest canopy. Significant isoprene fluxes were observed only during daytime, following diurnal cycles with midday net emission fluxes from the canopy ranging between 2.0 and 9.7 mg m$^{-2}$ h$^{-1}$. Net isoprene normalized flux (at 30°C, 1000 µmol quanta m$^{-2}$ s$^{-1}$) was estimated at 7.4 mg m$^{-2}$ h$^{-1}$. Evidence of direct emission of methanol was also found exhibiting maximum daytime fluxes ranging between 0.2 and 0.6 mg m$^{-2}$ h$^{-1}$, whereas flux values for monoterpenes and others OxVOC such as acetone and acetaldehyde were below the detection limit.

The MVK+MACR-to-isoprene ratio provided useful information on the oxidation of isoprene, and is in agreement with recent findings proposing weak production yields of MVK and MACR, in remote forest regions where the NOx concentrations are low. In-canopy chemical oxidation of isoprene was found to be weak and did not seem to have a significant impact on isoprene concentrations and fluxes above the canopy.

1 Introduction

Volatile organic compounds (VOCs) are emitted into the atmosphere from natural sources (biogenic emissions) as well as from anthropogenic sources. Biogenic VOCs (BVOCs) constitute approximately 90% of global VOC emissions (Guenther et al., 1995). These emissions are characterized by a strong chemical diversity with more than a thousand BVOCs identified as emitted by plants. However, only a few
of them contribute significantly to the global BVOC fluxes into the atmosphere (Laohawornkitkul et al., 2009). Iso-
prene (C₅H₈) is the most abundant BVOC in the Earth sys-
tem, accounting for about half of all natural VOCs emitted
at about 10¹⁵ g(C) year⁻¹ (Guenther et al., 2012). Mono-
terpenes, sesquiterpenes but also oxygenated compounds, such
as methanol, acetone and acetaldehyde may also be im-
portant regarding atmospheric chemical processes (Guen-
ther et al., 1995; Kesselmeier et al., 1998; Kesselmeier and
Staudt, 1998; Fuentes et al., 2000; Park et al., 2013). Despite
their relatively low atmospheric concentrations BVOCs are key
components of tropospheric chemistry. Due to their high re-
activity, they are rapidly oxidated by agents such as the OH
radicals, thus significantly influencing the oxidizing capac-
ity of the atmosphere and thereby impacting the residence
time of air pollutants and the most reactive greenhouse gases
such as methane (Wuebbles et al., 1989; Chiemchaisri et
al., 2001). BVOCs also play a key role in the tropospheric
ozone cycle. In the presence of sufficiently high NOₓ con-
centrations and light, BVOC emissions may be important
precursors of regional-scale O₃ (Trainor et al., 1987; Jacob
and Wofsy, 1988; Chameides et al., 1988; Lee et al., 2006;
Curci et al., 2010). As BVOC emissions increase with ambi-
etent light and temperature, the expected progression of cli-
mate change may impact BVOC emissions and contribute
to regional O₃ changes, but several processes still need to
be better understood. BVOCs not only influence gas phase
atmospheric chemistry; several studies have demonstrated
that the oxidation of monoterpenes, sesquiterpenes and, and,
to a lesser extent, of isoprene, contributes to the formation of
secondary organic aerosols (SOAs) in the troposphere (Griff-
fin et al., 1999; Claeys et al., 2004). The contribution esti-
mate of BVOCs to SOA formation is still rather uncertain:
(Andreae and Crutzen, 1997) calculated this contribution to
be in the range of 30–270 Tg yr⁻¹ whereas more recently
Tsigeridis and Kanakidou (2003) estimated a smaller range
of 2.5–44.5 Tg yr⁻¹.

In the Mediterranean region, the emissions and reactivity
of BVOCs are enhanced due to high temperatures and
sunny conditions and therefore are of particular interest for
the production of SOA and O₃. A modelling study performed
by Curci et al. (2010) predicts that, during summer in the
Mediterranean region, BVOC emissions may be responsi-
ble for an increase of daily O₃ maxima by 5 ppbv, whereas
Richards et al. (2013) estimated that a 20 % cut in local
BVOC emissions would lead to an average reduction of only
0.96 ppbv of O₃ over the Mediterranean.

To evaluate the contribution of VOCs emitted by vegeta-
tion in the Mediterranean area to O₃ and SOA formation, a
first step is to have accurate information on the amount of
BVOCs released into the atmosphere. In this objective, we
need to improve our knowledge regarding interactions be-
tween the terrestrial biosphere and the atmosphere. These in-
teractions are still poorly understood and quantified. Several
experimental studies demonstrated that a potential loss of
BVOCs through chemical reactions and deposition inside the
canopy could reduce the net fluxes into the atmosphere (Ci-
ccioli et al., 1999). The loss of isoprene for example, within
the canopy, could reach up to 40 % (Makar et al., 1999). A
few studies have also used Lagrangian-based stochastic mod-
els to explore the effect of chemical degradation of BVOCs
inside the canopy (Strong et al., 2004; Rinne et al., 2012).
Based on the Lagrangian approach along with measurements
of oxidants on a Scots pine site, Rinne et al. (2012) sug-
gested that in-canopy chemical degradation was negligible
for isoprene but had a major effect on fluxes of most reactive
species such as β-caryophyllene. Yet, those intra-canopy re-
actions are generally not considered in global vegetation or
chemistry-transport models (Ciccioli et al., 1999; Makar
et al., 1999; Fuentes et al., 2000; Forkel et al., 2006). There-
fore, there is a need for more experimental data and analy-
sis to quantify the impact of intra-canopy processes, together
with a modelling approach in order to evaluate the related er-
ror in the estimates of net BVOC fluxes to the Mediterranean
atmosphere.

A few studies have determined biogenic net emissions from
Mediterranean ecosystems (Seufert et al., 1997; Cicci-
oli et al., 1999; Darmais et al., 2000; Davison et al., 2009a).
During the first BEMA experiment (Biogenic Emissions in
the Mediterranean Area 1994) several field campaigns were
carried out at the Castelporziano site located on the Medi-
terranean coast near Rome, with one of the aims being to study
BVOC emission fluxes above various Mediterranean species
(Valentini et al., 1997). Emissions from orange plantations
have also been studied in Spain within the framework of the
second BEMA project 1997, and have shown an important
loss of very reactive compounds such as sesquiterpenes due
to within-canopy removal (Ciccioli et al., 1999) contrary to
the low chemical destruction on the less reactive monoter-
penes (Darmais et al., 2000).

Among the different tree species that characterize Mediter-
nanean ecosystems, Quercus pubescens Willd. is of partic-
ular interest because of its large spatial coverage (being
the most important tree species covering 20 % of the veg-
etated surface, i.e 260 000 ha, in the Provence–Alpes–Côte
da’Azur region) and high isoprene emission potential. Keenan
et al. (2009) estimated that the contribution of Q. pubescens
to the total European isoprene emissions budget exceeded
15 % for the 1960–1990 periods. Only a very limited number
of BVOC flux measurements have been performed on a Q.
pubescens ecosystem. Simon et al. (2005) measured fluxes
during one day using an aerodynamic gradient method in the
forest of Montmeyan, while Baghi et al. (2012) used the dis-
joint eddy covariance method at the Observatoire de Haute
Provence, both studies focusing exclusively on isoprene.

The originality of the CANOPEE ANR-JCJC project
is to combine field experiments (branch-scale to canopy-
scale measurements), targeting a large variety of BVOCs
over a Q. pubescens forest, with modelling. Experimental
data and observations collected during the intensive field
campaigns will eventually be used in a one-dimensional canopy-chemistry model CACHE (Forkel et al., 2006) and a regional chemistry-transport model, CHIMERE (Schmidt et al., 2001; Szopa et al., 2009). Through these models, both, the in-canopy processes and the role of local forested areas on the atmospheric chemical composition are studied for the Mediterranean region.

Our work consisted in measuring ambient BVOCs inside and above the O₂HP canopy during an intensive campaign (June 2012). The objectives of this work were (1) to identify and quantify the VOC species locally emitted at the Observatoire de Haute Provence, (2) describe the temporal variation of their mixing ratios, (3) assess net fluxes of BVOC from the canopy to the boundary layer and (4) to discuss the isoprene fluxes and isoprene potential loss due to in-canopy oxidation.

2 Methodology

2.1 Site description and general strategy

The Observatoire de Haute Provence is an astronomical observatory located in southeastern France (5°42'44"E, +43°55'54"N) on a plateau at a height of about 650 m. The Oak Observatory at the Observatoire de Haute Provence (O₂HP, https://o3hp.obs-hp.fr) is an experimental station dedicated to the observation of a deciduous oak ecosystem in relation to climate change. The site, is dominated by downy oak (Quercus pubescens Willd) and Montpellier maple (Acer monspessulanum L.) representing 75 and 25 %, respectively, of the foliar biomass of the overstorey tree species. The trees are about 70 years old and of an average height of 5 m. Understorey vegetation is dominated by European smoke bush (Cotinus coggyria Scop.) and many thermophilic and xerophilic herbaceous and grass species. The average single-sided leaf area index (LAI) measured (LAI-2000, Li-Cor, Lincoln, NE, USA) in August 2010 is 2.4. Flux footprint, i.e. the area of cumulative contribution to flux, was computed (online at http://www.footprint.kljun.net/) based on stability conditions, measurement height and roughness length (Kljun et al., 2004). Ninety percent of the along-wind footprint was calculated to include an area of 60 m for low-turbulence conditions ($u^* = 0.2$ m s$^{-1}$ and standard deviation of vertical velocity fluctuations, $\sigma_w = 0.5$ m s$^{-1}$) and 120 m for higher-turbulence conditions ($u^* = 1.2$ m s$^{-1}$, $\sigma_w = 1.4$ m s$^{-1}$).

The climate is sub-Mediterranean with warm-to-hot, dry summers and mild-to-cool, wet winters. During the field campaign the daily maximum temperatures typically ranged between 18 and 30 °C.

Monthly diurnal isoprene samplings have been conducted at the O₂HP over an 11-month period in order to characterize seasonal variations of ambient air concentration. During an intensive field campaign from 4 to 16 June 2012, measurements of BVOC, NO$_x$, and ozone concentrations, as well as flux measurements of individual VOC species, were performed. In addition to atmospheric measurements, BVOC emission rates at the branch scale were measured using dedicated chambers, and are described in the companion paper (Genard-Zielenkis et al., 2014).

2.2 Monthly isoprene sampling on cartridges and GC-MS analysis

Prior to the intensive field campaign, the seasonal variation of isoprene was followed inside the canopy. Air samples were collected on a monthly basis between May 2011 and December 2011 and from April 2012 to June 2012. Air was collected onto cartridges using an autosampler (SASS, TERA Environnement, Crolles, France). Commercially packed cartridges consisted of stainless-steel tubes filled with Tenax TA adsorbents. For a single sequence, 12 cartridges collected a volume of 700 mL of air during 2 h. The air entering the cartridge was filtered in order to eliminate any particulate matter. Each sampling tube was kept refrigerated at 4 °C and analysed at the laboratory within a month. The GC-MS analysis system consisted of an automatic desorption system (ATD 300, TurboMatrix, Perkin Elmer), coupled to a GC (Varian Model 3800, Varian Inc., USA) linked to an ion trap mass spectrometer from the same company. Blank cartridges were analysed every three or five samples and showed no significant levels of isoprene. An external multi-point calibration was performed by doping the adsorbent tubes with a VOC standard (National Physical Laboratory, Teddington, Middlesex, UK). The quantification limit was less than 140 pptv.

2.3 Ambient air sampling system during the intensive field campaign

Ambient air sampling was conducted at two different heights: 2 m above ground level (a.g.l.) inside the canopy, and above the top of the canopy at about 10 m. Both sampling inlets were slightly heated to about 1 °C above ambient temperature with a thermocouple type K in order to prevent water condensation. The lines were protected from radiation and attached to a pump-up mast, situated at 30 m from the van where all instruments were housed.

At 2 m a.g.l., air was pulled through a 35 m Teflon line (PFA, 1/2” outside diameter “OD” and 3/8” inner diameter “ID”) at about 40 L min$^{-1}$. Side flows were taken from a manifold at the end of the main line through thinner Teflon lines (PFA, 1/4” OD, 5/32”ID) and sub-sampled by a range of gas analysers (GC-FID, NO$_x$ and ozone analysers).

At 10 m a.g.l., air was pulled through a 45 m Teflon line (PFA, 1/2” OD, 3/8” ID) at a higher flow (~ 64 L min$^{-1}$) in order to maintain the turbulent flow (Reynolds number = 9440) needed to minimize signal attenuation. A proton transfer reaction mass spectrometer (PTR-MS) and a CO$_2$/H$_2$O analyser (IRGA LI-7500, Li-Cor, Lincoln, NE, USA) sub-sampled continuously at a flow rate of 80 and
Concentrations and fluxes of VOCs above the canopy were processed in the real time with a PTR-MS (serial number: 10-HS02 079, 2010, Ionicon Analytik, Innsbruck Austria), a technique which has been described in recent reviews (De Gouw and Warneke, 2006; Blake et al., 2009) and references therein. Briefly, the PTR-MS used was a high-sensitivity ion–molecule cluster. We operated the drift tube at 2.2 mbar pressure, 60°C temperature and 600 V voltage, to achieve an E/N ratio of approximately 132 Td (E: electric field strength [V cm⁻¹], N: buffer gas number density [molecule cm⁻³]; 1 Td = 10⁻¹⁷ V cm²). The primary H₂O⁺ ion count assessed at m/z 21 ranged between 0.9 × 10⁷−1.9 × 10⁷ cps with a typically < 5 % contribution from the monitored first water cluster at m/z 37 and < 4 % contribution from the oxygen O₂⁻ at m/z 32.

A first series of measurements in scan mode enabled us to browse a wide range of masses (m/z 21–m/z 206) and to set the PTR-MS measurement procedure for the rest of the field campaign. Above m/z 93, the only significant signal observed was at m/z 137.

The PTR-MS measurement procedure consisted of an hour-long sequence. In order to provide both flux data and information on the full VOC composition, the PTR-MS was automatically set to run continuously in two different modes: twice 25 min in flux mode and twice 5 min in scan mode during each hour. During the flux mode, eight protonated target masses (m/z 33, 45, 59, 61, 69, 71, 87 and 137) were measured successively with a dwell time of 500 ms per mass, while the primary ion count (m/z 21), the first water cluster ion count (m/z 37) and the photon “dark counts” (m/z 25) were all measured with a dwell time of 200 ms. This resulted in a total cycle time of 4.6 s and a total of n ≈ 326 recorded values per 25 min flux period. The remaining 10 min of each hour were used to obtain basic concentration information across the mass spectrum (5 min), and to monitor the instrument background (5 min). The PTR-MS background for each mass was monitored by sampling zero air (Ionimed’s GCU zero air generator) and was subtracted during post-processing. As each scan mode was set to 5 min and to a dwell time of 500 ms, the mass range was limited to m/z 21–93, in order to have at least five data points for each mass per cycle.

PTR-MS data were stored alongside those from the sonic anemometer, using a custom logging program written in LabVIEW (National Instruments, Austin, Texas, USA) as previously implemented by Langford et al. (2009).

2.4.2 Calibration and volume mixing ratio (VMR) calculations

The PTR-MS was calibrated on the first and the last days of the field campaign using a Gas Calibration Unit (GCU, Ionimed Analytik GmbH, Innsbruck, Austria), a dynamic gas dilution system that provides defined and controllable concentrations of different VOC using VOC-free air produced from ambient air with the GCU catalyst (Singer et al., 2007).

The commercial internal gas canister provided by Ionimed contained a mixture of 17 VOCs. The species used for the calibration were methanol (contributing to m/z 33), acetaldehyde (m/z 45), acetone (m/z 59), isoprene (m/z 69), crotonaldehyde (m/z 71), 2-butane (m/z 73), benzene (m/z 79), toluene (m/z 93) and α-pinene (m/z 137). The VOC concentrations in the standard gas were diluted (eight dilution steps) from an initial mixing ratio of 1 ppmv to a mixing ratio of 20 ppbv. Calibration coefficients, also called normalized sensitivities (S_{norm}) were calculated for each atomic mass unit (amu, m/z) using the approach of Taipale et al. (2008). As methylvinylketone (MVK) and methacrolein (MACR) were not included in the gas standard, we used the sensitivity of their structural isomer crotonaldehyde. The sensitivity of α-pinene was used for the sum of total monoterpenes. Sum of monoterpenes have been commonly quantified based on both molecular ion (m/z 137) and fragment ions (m/z 81). In this study, total monoterpenes were only calibrated against m/z 137. As considerable monoterpene fragmentation is expected for an E/N ratio of 132 Td, the abundance of the molecular ion (m/z 137) is expected to decline in favour of the fragment ions (dominant at m/z 81). Also, as fragmentation patterns are dependent on the different monoterpenes species present, the sensitivity of m/z 137 can slightly change if the monoterpenes composition is variable (Miształ et al., 2013). Nevertheless, additional measurements performed with cartridges have shown that α-pinene was the dominant terpene (80 ± 13 %) and therefore calculated sensitivity of total monoterpenes from m/z 137 is justified (see the Supplement).

The differences in sensitivities from the two PTR-MS calibrations were below 5 % for the compounds most discussed in the paper (methanol, acetaldehyde, acetone, isoprene and MVK +MACR). Higher differences of 9.36, 12.51 and 20.19 % were observed for benzene, toluene and monoterpenes respectively.

The mean values of normalized sensitivities determined from both gas calibration are given in Table 1, together with the detection limits, calculated as two times the standard deviation of the normalized background counts when measuring from the catalytically converted “zero” air. For
Isoprene for example, can fragment in the PTR-MS instrument and yield m/z 41. During this study, the fragmentation of isoprene in the PTR-MS instrument was small; more than 80% remained on the parent ion (m/z 69). Considering that the m/z 69 to m/z 41 ratio is constant (for a fixed E/N value), quantification of isoprene based on m/z 69 should not be affected by fragmentation.

Isoprene can suffer from interference with isomers such as furans (Christian et al., 2004). However, as the site is not impacted by significant sources of anthropogenic pollution, furan interference was expected to be negligible. Eventually, fragments of 2- and 3-methyl butanal and 2-methyl-3-buten-2-ol (MBO) can also contribute to the ion channel m/z 69. Despite the possibility of these multiple interferences at m/z 69, an inter-comparison showed a good agreement between PTR-MS and GC-FID, with a difference within the uncertainty range of both instruments (see Sect. 2.7). Considering the magnitude of isoprene emissions, it is very unlikely that any interference was significant.

As the GC-FID system deployed during the field campaign was designed for measuring exclusively hydrocarbons, no intercomparison with the PTR-MS was possible for the compounds attributed to C2–C6 O-VOC. For these compounds the discussion of potential interferences is therefore based on the literature.

Methanol, detected at m/z 33, is expected to exhibit only little fragmentation but can suffer from interferences with the oxygen isotope $^{16}$O$^{17}$O detected at the same mass (De Gouw and Warneke, 2007; Taipale et al., 2008). Minimal interferences are also expected at m/z 45, which is attributed to acetaldehyde. Acetone and propanal are both detected at m/z 59 in PTR-MS, but previous studies showed that the contribution from propanal is typically only small (0–10%) (De Gouw and Warneke, 2006) and confined to urban and industrial areas; the measurement at m/z 59 can therefore be regarded as a measurement of acetone. Signals at m/z 61 include mainly acetic acid and glycolaldehyde but can also suffer interferences from ethyl acetate fragments originated from industrial emissions (Christian et al., 2004; De Gouw and Warneke, 2007; Haase et al., 2012; Yuan et al., 2013) The isomers methylvinylketone (MVK) and metacrolein (MACR) were detected at the same mass-to-charge ratio, m/z 71. Until recently, the C4H4O+ ions have been exclusively attributed to the sum of the former compounds (Blake et al., 2009; De Gouw and Warneke, 2007). New evidence suggests additional contribution from other isoprene oxidation products, believed to be mostly organic hydroperoxides, that fragment at the same m/z ratio as the product ions of MVK and MACR, especially for low-NOx conditions (Liu et al., 2013). As isoprene hydroperoxides are expected to have similar diurnal variability to MVK and MACR, it is particularly difficult to estimate the contribution of isoprene hydroperoxides to m/z 71. Thus, we have to keep in mind that the concentration attributed to MACR and MVK might be slightly overestimated.

2.4.3 Identification of VOC and mass interferences

Standard PTR-MS instruments operate with a unit mass resolution and therefore cannot easily distinguish isobaric molecules. Furthermore, the formation of cluster ions and fragmentation of product ions may complicate the interpretation of PTR-MS mass spectra.

Table 1. Normalized sensitivities derived from the gas calibration. Limit of detections calculated as two times the standard deviation of the noise (ncps) divided by the normalized sensitivity.

methanol, instrument background counts were generally high and therefore the ambient measurement signal was relatively high as well. However, all data points for methanol, and also acetone exceeded the detection limit. Approximately 9% of m/z 45, 15% of m/z 71, 20% of m/z 73 and m/z 75 and 35% of m/z 61 data points were below the detection limits, usually found at night or just before sunrise. As the background counts of m/z 137 were not measured in the scan mode, they were derived from the calibrations, when the instrument was zeroed with catalytically converted air. The dwell time on each mass was 2000 ms during the calibration (instead of 500 ms during ambient measurements), thus, the background at m/z 137 might have been slightly underestimated. Ambient mixing ratios of monoterpenes followed at m/z 137 ranged between 0 and 0.26 ppbv and only 58% of the data points exceeded the detection limits.

Various techniques for statistical analysis of data below the detection limits have been developed and used. Most of these methods have advantages and disadvantages. A simple approach, commonly used, consists in replacing values below the Limit of Detection (LOD), with one-half their respective detection limits (Clarke, 1998). However, this substitution method can result in bias, either high or low depending on the value substituted (Helsel and Hirsch, 1992). In this study, all the compounds were considered representative in their full data set, and no data points have been removed or substituted.
The major contribution at mass channel \( m/z \) 73 is expected to originate from methylethylketone and methylpropanal, whereas the signal at \( m/z \) 75 could correspond to hydroxyacetone (Karl et al., 2007). However, potential interferences have been previously reported from butanal at \( m/z \) 73 and butanol and propionic acid at \( m/z \) 75 (De Gouw and Warneke, 2007; Karl et al., 2009) and no further investigation was made during this work to quantify these potential interferences. Total monoterpenes can be detected predominantly on the parent \( m/z \) 137 and the fragment \( m/z \) 81 ions. In this study, monoterpene concentrations were calculated based on the \( m/z \) 137 signal.

2.5 Flux calculations

Flux measurements of individual VOC species were performed using the micrometeorological disjunct eddy covariance by mass-scanning (DEC-MS) method, also referred to as the virtual disjunct eddy covariance technique (vDEC). DEC-MS and the conventional eddy covariance (EC) method rely on the same principle — that is, when the boundary layer is fully turbulent, the net vertical transfer is due to eddies. The flux of each compound is therefore calculated as the covariance between the vertical wind speed \( w \) and the VOC mixing ratio \( c \):

\[
F = \frac{1}{n} \sum_{i=1}^{n} w'(i - \tau_{tw}) \cdot c'(i),
\]

where \( w'(= w - \bar{w}) \) and \( c'(= c - \bar{c}) \) are the instantaneous fluctuations about the mean vertical wind and the mean VOC concentration respectively, \( n \) is the number of PTR-MS measurements during each 25 min averaging period (here, \( n = 326 \)), \( \tau_{tw} \) is the variable lag time that exists between wind and PTR-MS measurements resulting from the sample transit through the sampling line, and \( \Delta_{tw} \) is the sampling interval of the vertical wind velocity measurements (20 Hz = 0.05 s). Further details can be found in Rinne et al. (2001), Karl et al. (2002) and Langford et al. (2009). Output files from the logging program containing 30 min arrays of wind and PTR-MS data (25 min) were post-processed by an algorithm written in LabVIEW by Langford et al. (2009) in order to calculate the VOC fluxes. Each data row corresponding to a given VOC was converted to ppbv and to g m\(^{-3}\) using temperature and pressure values recorded at the site. Next, each VOC concentration data \( c \) was paired with the corresponding vertical wind velocity \( w \). The lag time between \( w \) and \( c \) resulting from the sample residence time in the sampling line was variable due to fluctuations of temperature and pressure. For each 25 min period, lag time \( \tau_{tw} \) was automatically determined for each compound using the maximum covariance method between the VOC concentration \( c \) and the vertical wind speed \( w \) (Taipale et al., 2010). For isoprene, a maximum covariance typically occurred around 15 ± 0.6 s. Based on isoprene results, MVK+MACR maximum covariance was searched within a window between 14 and 16 s. Due to its sticky nature, methanol showed slightly longer lag times with a mean value of 16.2 ± 1.4 s. The experimental mean time lag of each compound was used as the default value when we found no maximum in the covariance function. The post-processing algorithm also filtered out data which did not meet specific quality criteria:

1. VOC flux data recorded during periods of low turbulence. The lower limit of friction velocity \( u_\tau \) was set to 0.15 m s\(^{-1}\), a threshold commonly used in eddy covariance routine tests (Langford et al., 2010; Misztal et al., 2011).

2. VOC flux values below the detection limit. The detection limit was calculated as three times the standard deviation of the covariance for \( \tau_{tw} \) far away from the true lag (+150–180 s) (Spirig et al., 2005).

3. Non-stationary data. A stationary test, as suggested for the first time by Foken and Wichura (1996), was applied where the 25 min flux was disaggregated into 5 min blocks and the average of these compared to the 25 min flux. When the difference \( \Delta s \) between the average of the 5 min blocks and the 25 min flux was above 60 %, data were considered as non-stationary. Time series where the fluxes differed between 30 and 60 % were considered stationary, but of low quality. When the fluxes differed by less than 30 %, the data were considered as high-quality stationary data.

In the current study, 30 % of isoprene, 29 % of methanol and 60 % of MVK+MACR data points were rejected. Of the data that passed the quality assessment, more than 80 % were ranked as high quality. More statistics about these tests are presented in Table 3.

BVOC fluxes were corrected for high-frequency losses using the following equation:

\[
F_{\text{non-attenuated}} = F_m \cdot f_c = F_m \cdot \left(1 + \left((2\pi \times \tau \times n_m \times \bar{u})/(z - d)^2\right)\right)^\theta,
\]

where \( F_m \) is the measured flux, \( F_{\text{non-attenuated}} \) is the non-attenuated flux, and \( f_c \) is the correction factor (Horst, 1997; Davison et al., 2009b). \( f_c \) was calculated as a function of \( \tau \), the response time of the PTR-MS (here 0.5 s), \( z \) the measurement height (10 m), \( d \) the displacement height (2/3, \( h_c \)), where \( h_c \) is the canopy height, and \( \bar{u} \) the average wind speed at the measurement height. For neutral and unstable stratification, the dimensionless frequency at the co-spectral maximum is \( n_m = 0.085 \) and \( \theta = 7/8 \). Over the whole measurement period, the attenuation correction ranged from 1.1 to 23 %, with a mean value of 13 %.

Eventually, the error introduced by disjunct sampling was estimated by comparing sensible heat fluxes calculated from continuous data with sensible heat fluxes calculated from disjunct series. In order to simulate the disjunct sampling protocol on sensible heat data, a LabVIEW routine was used to
average the wind and temperature data to match the sampling rate of the PTR-MS (2 Hz) and set the sampling interval to 4.6 s. The difference between EC and DEC heat fluxes was small, typically below 2%. Assuming similarity between the heat flux and our VOC flux, a 2% error was estimated and no additional corrections have been made on the VOC fluxes.

2.6 VOC measurements by gas chromatography

An automatic gas chromatograph (airmoVOC C2-C6, Chromatotec, Saint Antoine France) equipped with a flame ionization detector (GC-FID) suitable for the measurement of light hydrocarbons, especially for isoprene, sampled at 2 m a.g.l. For each half-hour analysis, 250 mL of ambient air was drawn into the system via a stainless-steel inlet line with a flow rate of 18 mL min\(^{-1}\) (air sample integrated over 10 min). The air sample passed first through a Nafion dryer in order to remove the humidity and then hydrocarbons were pre-concentrated on a trap filled with Carboxen, Carbopack B and Carbotrap C. The trap was cooled to \(-8^\circ\text{C}\) by a cell with Peltier unit during the sampling procedure. Then, the pre-concentrated air sample was thermally desorbed at 220°C and injected on-column into a metal capillary column (Porous Layer Open Tubular Column PLOT, Al\(_2\)O\(_3\)/KCl; 0.53 mm inner diameter and 25 m length, Varian Inc) located inside the heated oven of the GC. The column temperature was programmed to maintain 40°C, and then to heat up at a rate of 20°C min\(^{-1}\) up to a final temperature of 203°C. Non-oxygenated C\(_2\)–C\(_6\) hydrocarbons (mainly isoprene during the measurements) were finally detected and quantified by a FID. A certified standard gas mixture (National Physical Laboratory, Teddington, Middlesex, UK) containing a mixture of 17 VOC at about 4 ppbv, was used as calibration standard. A complete calibration was performed twice a week. Each calibration was repeated at least three times in order to test the repeatability of the calibration mixtures. Relative standard deviations for analysis of the calibration mixtures were in the range of 1–9%. The overall uncertainty was estimated to be better than 15%.

2.7 GC-FID/PTR-MS isoprene field comparison

An in situ comparison was carried out during the campaign between isoprene measurements by GC-FID and PTR-MS. Both instruments sampled air from the same line at 2 m a.g.l. The GC-FID integrated air sample over 10 min every 30 min. By contrast, the PTR-MS sampled air continuously and followed isoprene at m/z 69 with a dwell time of 500 ms and a total cycle analysis of about 1 min. Only samples for which the GC-FID sample trapping interval and the PTR-MS sample cycle overlapped were included and the PTR-MS measurement were averaged over the 10 min sampling integration of the GC-FID. As this exercise lasted 19 h, in total 38 points were used for this intercomparison. Overall a very good correlation was observed between both instruments \((R^2 = 0.92)\), with 10% higher values for the GC-FID, a difference which is within the uncertainty range. The intercomparison highlighted an average offset of +0.3 ppbv for the PTR-MS during night-time, which was not subtracted from the PTR-MS data points and may be due to interferences from other VOCs. This night-time offset has to be kept in mind but remains small compared to the average daytime isoprene concentrations (2.09 ppbv).

2.8 NO\(_x\), ozone and micrometeorological measurements

Nitrogen oxides (NO\(_x\)) and ozone concentrations were measured 2 m a.g.l. A flow of 920 mL min\(^{-1}\) was sub-sampled from the main line and directed to the NO\(_x\) analyser. Nitrogen oxides were monitored with a T200UP instrument (Teledyne Advanced Pollution Instrumentation, San Diego, California, USA) by ozone-induced chemiluminescence. A 30 min span calibration was performed every day using a dynamic dilution calibrator (T700 UP, API, USA) equipped with a programmable NO generator. The span calibration was automated to run 15 min of zero air (produced by the zero air generator T701H, API) followed by 15 min of NO measurements generated at 5 ppbv. A calibration at 10 ppbv of NO was performed once a week by measuring 30 min of zero air and 30 min of a certified standard gas mixture (Air Liquide, Cofrac certification).

Ozone was measured with an automatic ultraviolet absorption’s analyser API T400 (API, USA) which was calibrated prior to the field deployment with an internal ozone generator (IZS, API) and operated with a sample flow rate of approximately 740 mL min\(^{-1}\).

Meteorological parameters such as temperature and air humidity (CS215, Campbell Scientific, UK) as well as photosynthetically active radiation, PAR (LI-190, Li-Cor, Lincoln, NE, USA), profiles inside the canopy were continuously monitored. The sonic anemometer (HS-50 Hz, Gill Instrument, Hampshire, UK) enabled the measurement of wind speed and direction and to calculate the friction velocity \(u^*\).

3 Results

3.1 Ambient isoprene seasonal variations

Figure 1 depicts the diurnal and seasonal variations of ambient, in-canopy, isoprene concentrations at the O3HP from May 2011 until May 2012. One or two complete diurnal cycles were taken every month. Even if the values reported here are representative only for the specific sampling days, significant seasonal variations of isoprene concentration were observed and were in agreement with the dependency of isoprene emission as a function of ambient light and temperature (Guenther et al., 1993). As conditions have been warmer in springtime than in summertime, maximum isoprene concentrations have been observed at the end of May with a maximum value of 8 ppbv. Lower concentrations were measured
on 14 and 31 July (maximum values of 4–5 ppbv) followed by a new increase in the end of August (9.8 ppbv); concentrations then decreased during the autumn when the leaves of the downy oak were still persistent and no significant isoprene concentration above detection limit was detected after November.

3.2 Air chemical regime

During the campaign the O₃HP site was typically under the influence of northerly wind regime. As depicted in Fig. 2, air masses were usually transported from the (north) western part of France and only some sparse events of southern winds occurred (5–7 June, 14–16 June). Very low NO levels (< 0.2 ppbv) were detected and no significant influence from anthropogenic NOₓ was observed (NO₂ < 3 ppbv). Likewise, CO concentrations were low throughout the study (< 180 ppbv). Benzene and toluene measurements, detected and used as tracers of anthropogenic pollution, showed background levels below 0.2 ppbv with the exception of one brief episode (7 and 8 June) when their concentration reached 0.8 and 1.6 ppbv (Fig. 3). During this episode the benzene-to-toluene ratio was slightly lower than for the rest of the measurement period and ranged between 0.3 and 0.8, indicating an influence of fresh anthropogenic air masses. As benzene and toluene have different lifetimes, the higher the benzene-to-toluene ratio the older is the air mass. Globally, the air masses encountered were not significantly impacted by anthropogenic primary emissions.

Relatively high ozone concentrations, typical of regions with strong photochemical activity such as the Mediterranean Basin, have been registered, with daily maximum ranging between 40 and 76 ppb.

3.2.1 Isoprene mixing ratios and above-canopy fluxes

The May–June 2012 time series of isoprene mixing ratios recorded simultaneously at 2 m (inside the canopy by GC-FID) and at 10 m height (above the canopy by PTR-MS) are shown in Fig. 3 along with air temperature and wind conditions. Isoprene exhibited high concentrations with an average mixing ratio of 1.2 ppbv above the canopy (Table 2). Among all observed VOCs, isoprene presented the largest amplitude between day- and night-time concentrations, this behaviour being typical of those biogenic compounds whose emissions are light and temperature dependent (Guenther et al., 1993; Goldstein et al., 1998). Night-time isoprene concentrations were close to our detection limit and started to increase steadily early in the morning, around 6.30 a.m. in response to the temperature and PAR increase. Maximum concentrations occurred in the afternoon, peaking between 2.0–5.0 ppbv and 2.0–16.9 ppbv at 10 and 2 m heights, respectively. In comparison, maximum atmospheric mixing ratios of about 10 ppbv were found during June above a Q. pubescens forest near Marseille (France) by Simon et al. (2005). A decrease in isoprene concentration was observed in the evening, as a consequence of isoprene emission dropping and the simultaneous consumption by OH radicals and diffusion. Isoprene mixing ratios continued to drop gradually during night-time and reached their minimum in the early morning.

The amplitude of the isoprene air concentration diurnal cycle varied strongly from day-to-day in response to environmental condition changes. By combining all the daytime isoprene data above the canopy, a stronger correlation was found with ambient temperature than with PAR. This relationship between daytime isoprene mixing ratios and temperature (at 10 m a.g.l.) was found to be exponential and the log linear fit of isoprene against temperature (°C) gave a relationship of $e^{0.1334 T}$ with a coefficient of determination, $R^2$, of 0.79. An exponential relationship was also found between isoprene mixing ratios and temperature measured at 2 m a.g.l (Fig. 4).

Throughout the measurement period a clear gradient in the vertical profile of isoprene concentrations was observable, with an average of 40% higher concentrations at 2 m than at 10 m a.g.l.

Isoprene fluxes measured during the campaign are shown in Fig. 5, along with PAR and $u_*$ measured simultaneously at 10 m. Between 10:00 and 17:00 local time, PAR ranged between 200 and 1550 µmol m⁻² s⁻¹ with an average of 1500 µmol quanta m⁻² s⁻¹. Among the measured compounds, isoprene showed by far the largest flux values with an average daytime emission of 2.77 mg m⁻² h⁻¹. Significant positive isoprene fluxes were only observed during daytime, following diel cycles with mid-day maxima ranging from 2.0 to 9.7 mg m⁻² h⁻¹. Isoprene fluxes reached zero after sunset or were rejected due to stratified conditions ($u_* < 0.15$ m s⁻¹).
3.2.2 MVK + MACR mixing ratios and above canopy fluxes

The sum of MVK and MACR (signal at \( m/z \) 71) had an average mixing ratio of 0.2 ppbv. Most of the days, MVK+MACR displayed a diurnal variability with daytime maxima ranging between 0.1 and 0.8 ppbv and night-time minima in the order of 20–40 pptv (Fig. 6). On the 6, 15 and 16 June, MVK+MACR did not exhibit the same diurnal trend as usually observed and its night-time concentration remained unusually high at 0.2–0.3 ppbv. These three nights (from 5–6, 14–15 and 15–16 June) were characterized by low winds and thermally stratified conditions: indeed, the temperature profiles inside the forest canopy exhibited a clear vertical gradient (of 4 °C in 5 m) with cooler temperatures close to the forest floor. MVK+MACR high concentrations can therefore be explained by weak vertical exchanges leading to their accumulation within and just above the canopy. This suggests that night-time removal was less efficient than the high deposition rates that have recently been reported for MVK/MACR (Karl et al., 2010; Misztal et al., 2011).

The present study showed a strong correlation \((R^2 = 0.84, \text{ slope } = 0.12)\) between MVK+MACR and isoprene during daytime hours (7 a.m. to 7 p.m), supporting that isoprene oxidation was responsible for the formation of the first-order oxidation products MVK and MACR. A delay of about 2 h in the morning rise of concentrations was observed and likely represents the time that isoprene needed to be degraded.

Fluxes of MVK+MACR showed a general trend of emission with diurnal cycles but are subject to considerable
Figure 3. Time series of VOCs and meteorological parameters recorded from 4 to 16 June. Benzene ($m/z$ 79), toluene ($m/z$ 93), methanol ($m/z$ 33), acetaldehyde ($m/z$ 45), acetone ($m/z$ 59), sum of acetic acid and glycolaldehyde ($m/z$ 61), total monoterpenes ($m/z$ 137) and isoprene ($m/z$ 69) were measured by PTR-MS above the canopy along with temperature and wind direction. Isoprene inside the canopy (2 m a.g.l) was measured by online GC-FID from 4 to 17 June.

Figure 4. Relationship between daytime isoprene mixing ratios (ppbv) and air temperature (°C). Data points and fit lines in green and blue correspond to measurements at 10 and 2 m height respectively.

Figure 5. Time series of MVK+MACR, methanol and isoprene fluxes along with friction velocity and PAR measured above the canopy from 4 June to 16 June. Flux error bars show ± standard deviation of the covariance for $h_{lag}$ far away from the true lag ($+150, -180$ s).
uncertainties (Fig. 5). Indeed as MVK+MACR fluxes were small the covariance function was noisy and the true peak in the covariance function was not easily identified and consequently half of the fluxes were below the detection limit (Table 3). Considering only positive values, fluxes never exceeded 0.10 mg m$^{-2}$ h$^{-1}$, which equates to 3% of the isoprene flux averaged over the same data points. Overall, MVK+MACR fluxes were weak and no reliable evidence of deposition was found.

3.2.3 Monoterpene mixing ratios

Due to the inability of the PTR-MS to distinguish isomer molecules, only the sum of all monoterpenes was measured. Overall, the vegetation at the O3HP was a weak monoterpene emitter. Ambient concentrations derived from $m/z$ 137 were low, with an average value of 0.06 ppbv and a maximum at 0.25 ppbv over the whole measurement period (Fig. 3). Whereas diurnal branch-level emission rates of monoterpenes were observed for oaks and maple trees (Genard-Zielinski et al., 2014), ambient concentrations at the canopy level did not exhibit a clear diurnal variability. At nights, especially when the turbulence was low, a build-up of monoterpenes was observed. Night-time concentrations were probably affected by remaining monoterpenes, emitted on the day before, and that have not been entirely consumed by daytime oxidants. Observed nocturnal maximum may also be attributed to nocturnal emissions from monoterpenes storing plants from the understorey vegetation. This nocturnal maximum is emphasized by the shallow nocturnal boundary layer, and the low concentrations of oxidizing species, leading to higher monoterpene concentrations.

Concentrations of monoterpenes might also be affected by advection of emissions from surrounding vegetation such as lavender or garrigue plants which are known to be monoterpene emitters (Owen et al., 2001; Boeckelmann, 2008).

3.2.4 Oxygenated VOC mixing ratios and fluxes

At the O3HP, several O$_x$VOCs were detected. Due to their relatively long lifetimes (see Table 1) and widespread sources, O$_x$VOCs showed elevated concentrations and less pronounced diurnal cycles than isoprene. Methanol was the most abundant VOC accounting for ~40% of the total measured VOC concentrations. Methanol mixing ratios at O3HP ranged between 0.7 to 5.5 ppbv (Fig. 3). Methanol’s relatively long atmospheric lifetime of ~10 days (Atkinson et al., 1999) resulted in elevated background concentrations (>0.7 ppbv). However, it was the only O$_x$VOC with a detectable net emission flux suggesting that local biogenic emissions also influence the observed concentrations. Methanol fluxes exhibited diurnal cycles with emission fluxes starting at sunrise, increasing during daytime as temperature and PAR increased, and stopping after sunset. Daily maximum methanol fluxes ranged between 0.20 and 0.63 mg m$^{-2}$ h$^{-1}$, i.e. about 5 to 20 times lower than the isoprene fluxes. Previous studies have shown both positive and negative fluxes of methanol. In comparison, a net deposition (up to 0.5 mg m$^{-2}$ h$^{-1}$) with few transient deposition events has been reported for a tropical rainforest in Costa Rica (Karl et al., 2004), whereas a net deposition for methanol has been reported in a Southeast Asian rainforest (Langford et al., 2010; Misztal et al., 2011). Our findings at the O3HP
indicated that the net exchange in methanol was positive. As above-canopy fluxes reflect the sum of production and removal processes, this does not mean that there was no bidirectional exchange, but that the component fluxes showing emission always overwhelmed the deposition components.

Among the other $O_x$VOCs detected were acetaldehyde ($m/z$ 45), acetone ($m/z$ 59) but also three compounds with a $m/z$ ratio of 61, 73 and 75, derived from the hourly 5 min scan. After methanol, acetone was the most abundant $O_x$VOC with atmospheric mixing ratios ranging between 0.6 and 2.5 ppbv. Acetaldehyde followed with slightly lower concentrations around 0.2–1.2 ppbv. It is striking that all of these mentioned $O_x$VOCs had a good covariance (Fig. 3) and most of them correlated well with each other. The strongest correlations were between $m/z$ 45 and $m/z$ 59 ($R^2 = 0.7$, slope = 0.78), $m/z$ 75 and $m/z$ 61 ($R^2 = 0.70$) $m/z$ 59 and $m/z$ 61 ($R^2 = 0.75$, slope = 1.2) but also $m/z$ 59 and $m/z$ 73 ($R^2 = 0.65$). Correlations with methanol were lower ($R^2 < 0.5$), likely due to its relatively strong biogenic source and also its high background. These significant correlations between every $O_x$VOCs could be the result of the boundary layer dynamics, but still suggest that they had a common source or that their formation mechanisms responded to environmental factors in a similar manner. For example, the good correlation between $m/z$ 75 and $m/z$ 61 suggests that these masses include important contributions from hydroxyacetone and glycolaldehyde, two second-generation products from isoprene. However, additional contributions from other compounds cannot be excluded.

From 5 to 7 June, changes in the wind direction were observed with air masses coming from the south and through the region of Marseille and Manosque. This southern wind shift was concurrent with the simultaneous increase of the region of Marseille and Manosque. This southern wind shift was concurrent with the simultaneous increase of concentrations for all monoterpenes. In western Italy, above a low macchia ecosystem, Davison et al. (2009) reported relatively small isoprene fluxes with mean daytime values of 0.097, 0.016 and 0.032 mg $m^{-2}$ h$^{-1}$ measured using the DEC method with three different PTR-MS. Furthermore, no significant isoprene fluxes were found above a pine–oak forest site in Italy and above orange plantations in Spain during the BEMA’s field studies (Velentini et al., 1997; Darmais et al., 2000). As the number of isoprene flux measurements at the canopy level in the Mediterranean region is limited, we extend our comparison to other ecosystems in the world. A non-exhaustive overview of isoprene flux measurements in Mediterranean, tropical, and temperate ecosystems is presented in Table 4. Reported values are displayed as found in the reference papers and demonstrate a difficulty of inter-comparison due to the multiple statistical ways of expressing the results (mean, median, range) used in every study. However, this table gives an idea of the orders of magnitude of isoprene emission rates at the canopy scale, and confirms that isoprene emissions from Mediterranean forests can be similar to or higher than those observed in other regions of the world which are dominated by isoprene-emitting vegetation. For instance, maximum isoprene fluxes of 6.1, 7.1, and 10.8 mg $m^{-2}$ h$^{-1}$ were observed respectively above a mature lowland in the central Amazon (Kuhn et al., 2007), a coniferous forest in eastern Belgium (Laffineur et al., 2011) or a deciduous forest in Germany (Spirig et al., 2005) and are very close to the maxima recorded at the $O_3$HP. Considerably higher isoprene fluxes reaching up to 30 mg $m^{-2}$ h$^{-1}$ were reported only from an oil palm plantation in Malaysia (Misz et al., 2011).

Isoprene fluxes at the $O_3$HP were also normalized to standard conditions (temperature and PAR at the canopy level of 30°C and 1000 µmol m$^{-2}$ s$^{-1}$ respectively) using the G93 algorithm (Guenther et al., 1993). By plotting all measured fluxes against the combined temperature and light scaling factors ($C_L$, $C_T$), a standardized flux $F_{\text{standard}}$ (or basal

4 Discussion on isoprene fluxes and in-canopy oxidation

4.1 Isoprene standardized flux and biomass emission factor

Isoprene fluxes presented in Sect. 3.2.1 confirm that emissions at the $O_3$HP are dominated by large isoprene fluxes. During the CANOPEE field campaign, the daily maxima of the isoprene fluxes ranged between 2.0 to 9.7 mg $m^{-2}$ h$^{-1}$ with a mean daytime flux of 2.0 mg $m^{-2}$ h$^{-1}$. This is in fairly good agreement with Baghi et al. (2012) who reported isoprene fluxes with values in the range 5.4–10 mg $m^{-2}$ h$^{-1}$ around midday, measured by DEC during a 2-day period in early August 2010 at the same site.

To our knowledge, above-canopy isoprene fluxes recorded at the $O_3$HP are the largest reported in the Mediterranean basin. Most of the VOC studies in this region were about monoterpenic emitters. In western Italy, above a low macchia ecosystem, Davison et al. (2009) reported relatively small isoprene fluxes with mean daytime values of 0.097, 0.016 and 0.032 mg $m^{-2}$ h$^{-1}$ measured using the DEC method with three different PTR-MS. Furthermore, no significant isoprene fluxes were found above a pine–oak forest site in Italy and above orange plantations in Spain during the BEMA’s field studies (Velentini et al., 1997; Darmais et al., 2000). As the number of isoprene flux measurements at the canopy level in the Mediterranean region is limited, we extend our comparison to other ecosystems in the world. A non-exhaustive overview of isoprene flux measurements in Mediterranean, tropical, and temperate ecosystems is presented in Table 4. Reported values are displayed as found in the reference papers and demonstrate a difficulty of inter-comparison due to the multiple statistical ways of expressing the results (mean, median, range) used in every study. However, this table gives an idea of the orders of magnitude of isoprene emission rates at the canopy scale, and confirms that isoprene emissions from Mediterranean forests can be similar to or higher than those observed in other regions of the world which are dominated by isoprene-emitting vegetation. For instance, maximum isoprene fluxes of 6.1, 7.1, and 10.8 mg $m^{-2}$ h$^{-1}$ were observed respectively above a mature lowland in the central Amazon (Kuhn et al., 2007), a coniferous forest in eastern Belgium (Laffineur et al., 2011) or a deciduous forest in Germany (Spirig et al., 2005) and are very close to the maxima recorded at the $O_3$HP. Considerably higher isoprene fluxes reaching up to 30 mg $m^{-2}$ h$^{-1}$ were reported only from an oil palm plantation in Malaysia (Misz et al., 2011).
emission rate) of 7.4 mg m$^{-2}$ h$^{-1}$ was derived from the fit line with zero intercept (Fig. 7).

For comparison, enclosure measurements for seven different branches of *Q. pubescens* at the O$_3$ HP during CANOPEE resulted in emission factors $E_{F_{biomass}}$ ranging between 30 and 140 µg g$^{-1}$ h$^{-1}$ (hereafter, µg g$^{-1}$ h$^{-1}$) with a median value of 70 ± 8 µg g$^{-1}$ h$^{-1}$ (Genard-Zielinski et al., 2014). The average $E_{F_{biomass}}$ was then upscaled to give an standardized flux $F_{standard}$:

$$F_{standard-upscaled} = E_{F_{biomass}} \times \sum_{h=0}^{h_c} LAI(h) \cdot LMA(h),$$

where $h$ is the distance above ground (unit: m), $h_c$ the canopy height, $LAI$ the mean leaf area index (unit: m$^2$ m$^{-2}$) and $LMA$ the leaf dry mass per unit area (unit: g m$^{-2}$). The resulting up-scaled basal emission rate $F_{standard-upscaled}$ was 18 ± 5 mg m$^{-2}$ h$^{-1}$. Fluxes estimated by extrapolating leaf-level measurements were twofold higher than the average figure derived from DEC measurements. We consider this to be a reasonably good agreement since a factor of 2 of difference can be expected when comparing techniques over different spatial scales, due to uncertainties in the extrapolation, in addition to the uncertainties of both measurements. A reason for the difference certainly arises also from the normalization of DEC fluxes to standard conditions using the air temperature and PAR above the canopy. Since a significant fraction of the canopy experiences lower light levels, the standardized emission flux using an above-canopy PAR is underestimated. For example, a normalization using an in-canopy PAR would lead to an $F_{standard}$ increase of about 100 %. On the other hand, the normalization using actual leaf temperature, which is usually a couple of degrees higher than ambient temperature, would lead to lower $F_{standard}$ values. A canopy structure model would be required to better quantify both effects. Additional uncertainty comes from the difference in biomass emission factors $E_{F_{biomass}}$, which can vary by more than a factor of 4 between tree individuals, as indicated by the branch-level measurements (Genard-Zielinski et al., 2014). Leaf level measurements are often performed on sun foliage, which has larger emission rates as compared to the whole crown. Further, an overestimation of basal emission rates based on leaf level emissions could be the chemical loss of isoprene within the canopy, which we tentatively examine hereafter.

### 4.2 Isoprene oxidation within the canopy

In recent years, much attention has been devoted to understanding isoprene chemistry, particularly in sites such as the O$_3$ HP, where the isoprene emissions are strong and the NOX levels are low (NO mean value ~ 25 ppt). Inconsistencies between observations in rural sites and model estimates of

$^1$ Fluxes normalized to standard conditions: 1000 µ mol m$^{-2}$ s$^{-1}$; 30 °C. $^2$ Values correspond to fluxes measured using the DEC method using three different proton transfer reaction mass spectrometers.
the ratio of isoprene to its oxidation products have pointed out uncertainties associated with the understanding of the mechanism of isoprene oxidation. Lately, laboratory studies have elaborated rate coefficients and product branching ratio yields (Paulot et al., 2009; Peeters et al., 2009; da Silva et al., 2009; Peeters and Müller, 2010; Fuchs et al., 2013). In the following section, we investigate the isoprene oxidation and production of MVK and MACR at the O$_3$HP and discuss our results with regard to recent findings that suggest very low production yields of MVK and MACR under low NO$_x$ conditions (NO < 70 ppt) (Liu et al., 2013).

OH-oxidation of isoprene is initiated by the addition of the hydroxyl radical to the double bonds of isoprene. The alkyl radical formed reacts with oxygen (O$_2$) to form alkyl peroxy radicals (HOC5H8OO$^+$), commonly called ISOPOO. ISOPOO radicals subsequently react either with NO (Tua- zon and Atkinson, 1990), hydroperoxy radicals HO$_2$ (Paulot et al., 2009), or organic peroxy radicals RO$_2$ (Jenkin et al., 1998). Additional isomerization reactions of ISOPOO radicals have also been suggested in the recent literature (Peeters et al., 2009; da Silva et al., 2010; Fuchs et al., 2013). At high NO$_x$ concentrations the dominant fate of ISOPOO is generally the reaction with NO. However, under low NO$_x$ conditions, reaction with HO$_2$ dominates and leads to lower MVK and MACR yields (Miyoshi et al., 1994; Ruppert and Becker, 2000). Using atmospheric simulation chambers, Liu et al. (2013) found the lowest MVK and MACR yields that have ever been reported, with values of (3.8 ± 1.3)% for MVK and (2.5 ± 0.9)% for MACR, i.e. more than 60% less than in previous “low-NO$_x$” studies (Miyoshi et al., 1994; Ruppert and Becker, 2000; Navarro et al., 2011), and about 10 times lower than via the NO pathway.

At the O$_3$HP, the 12 days of measurements featured a [MVK+MACR]-to-isoprene ratio of 0.13 ± 0.05 during daytime (Fig. 8). It has to be considered that this ratio could be lower if any interference occurred at m/z 71 from other oxidation products. Despite this possible overestimation, the [MVK+MACR]-to-isoprene ratio at the O$_3$HP is at the lower end of the range that has previously been observed in other ecosystems of the world. This ratio usually falls to around 0.3–0.75, and is dependent on the sampling height (Montzka et al., 1993; Biesenthal et al., 1998; Holzinger et al., 2002). Nevertheless, a few studies have shown ratios close to our estimates: a ratio of 0.12 has been reported in a rural forest of Michigan (Apel, 2002), and a ratio of 0.1 to 0.36 was obtained in a Southeast Asian tropical rainforest (Langford et al., 2010). The [MVK+MACR]-to-isoprene ratio reported here is in agreement with recent findings proposing weak production yields of MVK and MACR, in remote forest regions where the NO$_x$ concentrations are low.

The low [MVK+MACR]-to-isoprene ratio is also in agreement with the fluxes of mass 71 (related to MACR and MVK and possible contribution from isoprene hydroperoxides). Fluxes of mass 71 showed a general trend of emission, and thus suggest a production throughout the forest canopy. However, the magnitude of these fluxes was very low – about 40% being below the detection limit – and the data that passed all the quality assurance tests represented about 3% of the isoprene fluxes. Estimates of the isoprene that is oxidated to MVK+MACR below the sampling height of flux measurement are usually of the order of 5 to 15%, also depending on the measurement height (Stroud et al., 2005). Additionally to the low NO$_x$ conditions, which lead to low yields of MACR and MVK, minor chemical processing of isoprene is expected below the measurement height due to the canopy architecture of the O$_3$HP. The forest of the O$_3$HP is low (5 m height on average), well ventilated and therefore closely coupled to the boundary layer above. Thus, the turbulent transport time $\tau$ between ground surface and the measurement height was estimated to be around 30–60 s in daytime (see Supplement for calculation details). This is considerably faster than the isoprene chemical degradation estimated at about 4 h against its oxidation by OH for typical summer daytime. Thus, isoprene rapidly reaches the atmosphere and does not have the time to react in a significant way with OH radicals from the moment of its release by the vegetation and its arrival at the sampling inlet.

5 Conclusions

We have presented atmospheric measurements at high resolution for concentrations and direct above-canopy fluxes of BVOCs for a Mediterranean downy oak forest.

High concentrations of isoprene have been observed, with daytime maxima ranging between 2–17 ppbv inside the forest and 2–5 ppbv above the top of the canopy. Isoprene concentrations showed a clear diurnal cycle with a daytime maximum and a minimum in the early morning and at
night, respectively. Above the canopy, isoprene concentrations were about 40% lower than inside the canopy; this loss was attributed to physical processes such as mixing with isoprene-depleted air masses (or, conversely, the build-up of isoprene within the canopy). Isoprene fluxes at the O3HP site were among the largest fluxes reported in the Mediterranean region, with mid-day maxima ranging between 2.0 and 9.7 mg m⁻² h⁻¹. Based on these measurements, an isoprene basal emission rate of 7.4 mg m⁻² h⁻¹ is recommended for downy oaks in this region for biogenic emission models. O₃ VOCs were abundant at the site with mean daytime concentration of 2.48, 1.35 and 0.42 ppbv for methanol, acetone and acetaldehyde respectively. Of these compounds, only methanol exhibited significant fluxes, indicating a primary source inside the canopy. Methanol fluxes featured maxima daytime values ranging between 0.20 and 0.63 mg m⁻² h⁻¹, i.e. about 5 to 20 times lower than isoprene fluxes. No above-canopy fluxes of monoterpenes have been observed, and, as a result, ambient concentrations of monoterpenes were close to the detection limits. These observations are in agreement with a branch-level study, stating that Q. pubescens was a strong emitter of isoprene and weak emitter of monoterpenes (Genard-Zielinski et al., 2014).

At the forest site of the O₃HP, where the isoprene emissions were high and the NO₃ levels low, a small [MVK+MACR]-to-isoprene ratio has been observed (mean daytime value of 0.13 ± 0.05). Upward fluxes of MACR and MVK indicated a production from isoprene throughout the forest canopy, but represented less than 3% of the isoprene flux. Further, no systematic deposition fluxes could be detected for either of the investigated compounds. Therefore, we conclude that intra-canopy processes had a minor effect on above-canopy fluxes.

The Supplement related to this article is available online at doi:10.5194/acp-14-10085-2014-supplement.

Acknowledgements. We thank our colleagues for continuous support and discussion. We are grateful to the O₃HP team and especially to J. P. Orts and T. Gauquelin. We thank A. Bouygues for helping with the setup. This work is supported by the French National Agency for Research (ANR 2010 ICIC 603 01). We acknowledge the INSU (ChArMEx), ADEME, CNRS and CEA for supporting funding. The CEH contribution to the study was supported by the FP7 project ÉCLAIRE.
