Abstract. More than 2 years of columnar atmospheric aerosol measurements (2006–2009) at the Tamanrasset site (22.79° N, 5.53° E, 1377 m a.s.l.), in the heart of the Sahara, are analysed. Aerosol Robotic Network (AERONET) level 2.0 data were used. The KCICLO (K is the name of a constant and ciclo means cycle in Spanish) method was applied to a part of the level 1.5 data series to improve the quality of the results. The annual variability of aerosol optical depth (AOD) and Ångström exponent (AE) has been found to be strongly linked to the convective boundary layer (CBL) thermodynamic features. The dry-cool season (autumn and winter) is characterized by a shallow CBL and very low mean turbidity (AOD ∼ 0.09 at 440 nm, AE ∼ 0.62). The wet-hot season (spring and summer) is dominated by high turbidity of coarse dust particles (AE ∼ 0.28, AOD ∼ 0.39 at 440 nm) and a deep CBL. The aerosol-type characterization shows desert mineral dust as the prevailing aerosol. Both pure Saharan dust and very clear sky conditions are observed depending on the season. However, several case studies indicate an anthropogenic fine mode contribution from the industrial areas in Libya and Algeria. The concentration weighted trajectory (CWT) source apportionment method was used to identify potential sources of air masses arriving at Tamanrasset at several heights for each season. Microphysical and optical properties and precipitable water vapour were also investigated.

1 Introduction

The regional characterization of mineral dust, particularly close to source areas, has become a valuable tool for researchers from different fields. It will lead to reducing some existing uncertainties about direct radiative forcing by atmospheric aerosols (Forster et al., 2007), and to a better understanding about the potential impact of aerosol on human health and air quality (e.g. De Longueville et al., 2010; Perez et al., 2012).

The Sahara and its margins are the largest and most continuous dust sources in the world. Several satellite and ground-based observation analyses have led to identifying the base of the Ahaggar and Tibesti mountains and the Bodélé Depression as the major sources in this area (Goudi and Middleton, 2001; Prospero et al., 2002; Ginoux et al., 2012). During
recent years, several field campaigns in different locations focused on the analysis of Saharan dust features (Todd et al., 2013, and references therein). In particular, Tamanrasset (main city in the Hoggar, also known as Ahaggar Mountains, in Algeria) hosted a specific soil and aerosol sampling analysis at the beginning of the 1980s (D’Almeida and Schütz, 1983), the African turbidity monitoring network (1980–1984) for climate modelling purposes (D’Almeida, 1986, 1987), and the more recent African Monsoon Multidisciplinary Analysis (AMMA) campaign (Redelsperger et al., 2006).

During AMMA’s intensive observation periods in 2006, Tamanrasset was a fully equipped ground-based station for aerosol and radiation measurements. This campaign has provided comprehensive analysis of several features at Tamanrasset and the Hoggar Mountains (e.g. Flamant et al., 2007; Bou Karam et al., 2008; Cuesta et al., 2008, 2009, 2010). In addition, aerosol observations carried out at Tamanrasset in 2006 have been part of selected aerosol data sets used for several model validations (e.g. Toledano et al., 2009; Haustein et al., 2009, 2012; Su and Toon, 2011). In spite of these studies, limited aerosol observations, mainly confined to shorter period campaigns, are available for this area which is strategically located in the heart of the Sahara.

Consequently, Tamanrasset was considered to be a key place to initiate the Saharan Air Layer Analysis and Monitoring (SALAM) project as part of the Global Atmospheric Watch (GAW) twinning cooperation program between l’Office Nationale de la Météorologie (ONM, Algeria) and the Meteorological State Agency of Spain (AEMET, formerly INM) through the Izaña GAW station (Canary Islands, Spain). In the framework of this project, at the end of September 2006, a Cimel sun photometer was set up at Tamanrasset and integrated into the Aerosol Robotic Network (AERONET). In 2010 the station was incorporated into the World Meteorological Organization (WMO) Sand and Dust Storm Warning Advisory and Assessment System (SDS-WAS) Regional Center for Northern Africa, Middle East and Europe (http://sds-was.aemet.es/) for near-real time and long-term dust model evaluation. The new aerosol data set from Tamanrasset has been used for a preliminary characterization of aerosol properties (Guirado et al., 2011), for space-based remote sensing evaluation (e.g. Schuster et al., 2012), and for model validation (e.g. Tegen et al., 2013). Regarding dust optical properties, Kim et al. (2011) provide an analysis of the single scattering albedo, asymmetry parameter, real refractive index, and imaginary refractive index at several stations, including Tamanrasset from 2006 to 2009.

The present work focuses on a detailed characterization of aerosol properties at the Tamanrasset site. Very preliminary results, briefly shown by Guirado et al. (2011), have been carefully revised and extended taking into account corrected data. The KCICLO (K is the name of a constant and ciclo means cycle in Spanish) method has been used to correct the aerosol optical depth (AOD) and the Ångström exponent (AE) time series. Specific characterizations have been made for the first time: annual evolution and seasonal features of precipitable water vapour (PWV), fine mode fraction (FMF), and aerosol microphysics, as well as an identification of potential source regions. The paper is structured as follows: measurement site, data sets and tools used are described in Sect. 2. In Sect. 3.1 the main aerosol and PWV seasonal features are analysed, an aerosol-type classification is performed and microphysical and optical properties are discussed. In Sect. 3.2 the concentration weighted trajectory method is used to identify potential source regions. In Sect. 3.3 the transport of anthropogenic fine aerosols to Tamanrasset is discussed. In Sect. 4 the main concluding points are provided.

2 Methodology

2.1 Unique characteristics of the Tamanrasset site

On 30 September 2006, a sun photometer was installed on the roof of the main building of the Regional Meteorological Center (Direction Météo Régional Sud, Office National de la Météorologie, Algeria) at Tamanrasset (22.79° N, 5.53° E, 1377 m a.s.l.) in southern Algeria. Tamanrasset is free from industrial activities and is representative of pure desert dust aerosols (Guirado et al., 2011). It is near dust sources located in Mali, southern Algeria, Libya and Chad, on the northern edge of the zonal dust pathway identified by the MISR (Multi-angle Imaging SpectroRadiometer, onboard NASA’s Terra satellite) AOD retrieval (Fig. 8). Moreover, this geographical location is very significant since ground-based measurements of atmospheric constituents from continental Africa are very limited, especially in the surrounding area of Tamanrasset. This station is involved in several international measurement programs such as the Global Climate Observing System (GCOS) – Upper-Air Network (GUAN), the Baseline Surface Radiation Network (BSRN), and the GAW program of the WMO.

The climate of the region is modulated by the influence of the monsoon during summer and the westerly winds during the rest of the year (Cuesta et al., 2008). In July and August easterly winds, moist air masses and scarce rainfall are the prevailing weather conditions. In September the influence of the westerly winds appears at high altitude and draws successively closer to the ground until the end of autumn. This system is maintained, although wind strengths vary, during the winter and even springtime until June when the influence of the easterly winds starts in layers close to the ground (Dubief, 1979). The winter season is characterized by dry conditions and occasional midlevel and cirrus clouds (Cuesta et al., 2008).
2.2 Cimel sun photometer data set

2.2.1 AERONET data

The Cimel sun photometer (model CE-318 operating at 340, 380, 440, 500, 670, 870, 940 and 1020 nm nominal wavelengths) installed at Tamanrasset is one of the standard instruments in AERONET. Data acquisition protocols, calibration procedures and data processing methods have been extensively described (Holben et al., 1998; Dubovik et al., 2000; Smirnov et al., 2000; O’Neill et al., 2003). Solar extinction measurements are used to compute AOD at each wavelength, except for the 940 nm channel, used to retrieve PWV (Eck et al., 1999). AE, which is a measure of the AOD spectral dependence with the wavelength of incident light, is a qualitative indicator of the aerosols’ predominant particle size and it can be computed for two or more wavelengths (Schuster et al., 2006). For climatological studies, linear fit determination of AE in the 440–870 nm range is computed for three or four nominal wavelengths (440 nm, 500 nm when available, 670 nm, and 870 nm). AERONET FMF from the spectral deconvolution algorithm (SDA; O’Neill et al., 2003) has also been included in the present analysis. Furthermore, several aerosol microphysical and optical properties retrieved from the AERONET inversion algorithm (Dubovik and King, 2000; Dubovik et al., 2006) are discussed. Particularly, particle size distribution, volume concentration, effective radius, as well as single scattering albedo, asymmetry factor, and complex refractive index are analysed because they are closely related to aerosol radiative effects.

The AOD uncertainty is approximately 0.01–0.02 (spectrally dependent, with higher errors in the UV) and it alters the AE by 0.03–0.04 (Eck et al., 1999; Schuster et al., 2006). The PWV uncertainty is estimated to be ±10% (Holben et al., 2001). The amplitude of the errors of the derived parameters from SDA retrieval varies as the inverse of the total AOD. In addition to measurement errors, there are errors in the AOD retrieval due to the uncertainty in the assumed values of the spectral curvature in each mode (O’Neill et al., 2001), which are most critical in coarse mode-dominated conditions. Dubovik et al. (2002) provide a detailed description of the expected error in aerosol size distribution, complex refractive index, and single scattering albedo.

At present, AERONET level 2.0 data from Tamanrasset is only available from October 2006 to February 2009, except from 18 November 2007 to 20 June 2008. Data for the period February 2009–October 2012 will likely never be promoted to level 2.0, and level 1.5 data in this period do not have the sufficient quality to be properly corrected with the KCICLO method that will be discussed below. Data after November 2012 are expected to achieve AERONET level 2.0 and might be incorporated in the future to perform a relatively longer-term analysis. Long AOD data series fulfilling the highest quality criteria are difficult to obtain in remote stations such as Tamanrasset, in which the annual exchange of instruments is difficult, and where dust events lead to dust accumulating on the optics. Intense dust storms cause a rapid accumulation of dust while less intense dust transport leads to a more progressive build up of dust on the optics. These inconsistencies are difficult to correct and deteriorate the quality of the measurements.

2.2.2 KCICLO correction

The analysis of the AOD period from 18 November 2007 to 20 June 2008 reveals a systematic and strong AOD and AE fictitious diurnal cycle, most likely caused by dust on the sun photometer’s front windows (Guirado et al., 2011). Other possible causes, such as the effect of temperature on the detector and incorrect sun-pointing, were analysed and discarded. Measurements corresponding to 340 and 500 nm did not achieve level 2.0 in the entire analysed period due to the significant degradation of these filters.

The KCICLO method is used to detect, evaluate and correct possible calibration problems, after discarding a real atmospheric effect or instrument malfunctions (Cachorro et al., 2004, 2008a). Particularly, the obstruction in the optical path, due to dirt on the sun photometer’s front windows, leads to a distinct and artificial diurnal cycle pattern that can be corrected using the KCICLO method. This fictitious diurnal cycle is due to the systematic absolute error in the AOD measurements as a consequence of calibration errors (Romero and Cuevas, 2002): the magnitude of this absolute error is greatest at midday because it varies as the inverse of the solar air mass (Cachorro et al., 2008a). This method introduces a constant $K$ defined as the ratio between “incorrect” current and true calibration constants. $K$ quantifies calibration factor error in such a way that $K = 1$ corresponds to a correct calibration constant and $K > 1$ (or $K < 1$) will result in an overestimation (underestimation) of the current calibration constant and a convex (concave) curve shape in the diurnal cycle (Cachorro et al., 2004, 2008a). The relative differences of AOD between AERONET level 2.0 and KCICLO data series are estimated to be 8.5% (or about 0.01 in absolute AOD values) and 2.4% for AE (Cachorro et al., 2008b).

The application of this in situ correction-calibration procedure requires a sufficient number of clear-sky and stable days for a given period to be corrected. The selected days must fulfil a set of requirements about air mass range (higher than 4 and typically between 1.7 and 6), turbidity (AOD (440 nm) < 0.12 and variability lower than 5% in the specified air mass range), number of data points (at least 12 per day), and standard deviation of the fit to quantify the calibration factor error (lower than 0.01) (Cachorro et al., 2008a). Therefore, the successful application of the KCICLO method over a given period is associated with a sufficient number of days (5–10%) fulfilling all the above-mentioned requirements. As a consequence, the application of the method is not always feasible at all stations or at all periods of time. The KCICLO
method has been previously used to correct the AOD data series (e.g. Toledano et al., 2007; Barreto et al., 2014).

At Tamanrasset, a sufficient number of days (94) from 18 November 2007 to 20 June 2008 were available to properly apply the KCICLO method and complete the AOD/AE data set. This method confirmed a calibration shift between November 2007 and June 2008. Only two different correction periods, i.e. two different types of lens contamination (amount of dirt and lenses affected), were detected and the corresponding mean \( K \) values (Table 1) were computed. Part of the original and the corrected AOD and AE data for both periods is shown in Fig. 1. Note that the fictitious diurnal cycle is largely reduced both in the AOD and the derived AE.

Additionally, it was possible to apply an external quality control of the KCICLO correction. Since 1995, in the framework of the GAW program, a J-309 handheld sun photometer (Reddy, 1986) supplied by the National Oceanic and Atmospheric Administration (NOAA) has been operated at Tamanrasset. The photometer is characterized by a 2.5° full angle field of view and two 10 nm bandwidth filters centred at 386 and 506 nm, respectively. AOD measurements at 500 nm taken at 09:00, 12:00 and 15:00 UTC (universal time coordinated) were used in this work. Data from October 2006 to February 2009 were compared to the closest AERONET measurements at 440 nm (±15 min as time coincident criterion). The AOD measurement scatter plot between NOAA and three AERONET data sets is shown in Fig. 2 and the corresponding linear regression parameters are provided in Table 2. After applying the KCICLO correction the correlation coefficient increases to 0.981 for this period (0.968 before correction).

\(^a\) Data from 88 days fulfilling the requirements for applying the KCICLO method have been used to compute the mean \( K \) values for the first period and 6 days for the second one.
special features regarding the analysed AERONET inversion retrievals for single scattering albedo and complex refractive index will be discussed in Sect. 3.1.4. All the analysed daily, monthly, and seasonal averages have been calculated from the corresponding sun photometer single measurements.

2.3 Ancillary data

2.3.1 Meteorological radiosonde data

A GCOS-GUAN meteorological radiosonde (Vaisala RS92) is launched twice a day (at 00:00 UTC and 12:00 UTC) at Tamanrasset airport: data available at the University of Wyoming web site (http://weather.uwyo.edu/upperair/sounding.html). Radiosonde data at 12:00 UTC were used for calculation of the convective boundary layer (CBL) top altitude from 2006 to 2009. The criteria used to account for the overshooting thermals are \( \Delta \theta / \Delta z \geq 0.0025 \text{ K m}^{-1} \) and \( \theta_{\text{top}} - \theta_{\text{base}} \geq 1 \text{ K} \), where \( \Delta \theta / \Delta z \) is the potential temperature lapse rate and \( \theta_{\text{top}} \) and \( \theta_{\text{base}} \) refer to the top and base of the layer, respectively (Heffter, 1980; Cuesta et al., 2008). Additionally, PWV retrieved from radiosonde was compared with corresponding AERONET PWV as will be shown in Sect. 3.1.5. Estimated PWV precision of the radiosonde RS92 is around 5 % but for very dry conditions it is about 10–20 % (Miloshevich et al., 2009).

2.3.2 Aerosol extinction vertical profiles

The Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) is an elastic-backscatter lidar on board the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO). CALIOP emits linearly polarized light at 532 and 1064 nm to provide vertically resolved observations of aerosols and clouds on a global scale (Hunt et al., 2009; Winker et al., 2009). Aerosol extinction features at certain heights have been identified using CALIOP level 2 version 3.01 extinction profiles at 532 nm over Tamanrasset (within a 1.5° radius) with a vertical resolution of 60 m (below 20.2 km height) and a horizontal resolution of 5 km. Data from the period 2007–2008, downloaded from the NASA database (https://eosweb.larc.nasa.gov/cgi-bin/searchTool.cgi?Dataset=CAL_IIR_L1-Prov-V1-10), have been filtered following the methodology of Tesche et al. (2013).

2.3.3 Concentration weighted trajectory method

The concentration weighted trajectory (CWT) source apportionment method (Seibert et al., 1994; Hsu et al., 2003) was used to identify pathways of aerosol-laden air masses for the period 2006–2009 in the dry season (from November to February) and the wet season (from April to September). The resulting information about air mass pathways was combined with the information about aerosol source regions reported by several authors (Sect. 3.2, Fig. 8) to detect potential sources affecting Tamanrasset. This method combines data measured at the receptor site with air mass back trajectories. Although this method was originally designed and widely used for weighting trajectories with concentrations measured at a receptor site, we used AERONET daily AOD and AE observations at Tamanrasset to identify aerosol content and type, respectively. A similar approach to connect distinct sources with different aerosol types has been previously performed by other authors (e.g. Naseema Beegum et al., 2012). A weighted AOD or AE value is assigned to each grid cell by averaging the values associated with the trajectories crossing that grid cell:

\[
C_{ij} = \left( \sum_{k=1}^{N} n_{ijk} \right)^{-1} \cdot \sum_{k=1}^{N} C_k n_{ijk},
\]

where \( C_{ij} \) is the averaged weighted AOD or AE value in the \((i,j)\) grid cell, \( C_k \) is the AOD or AE value observed at the receptor point on arrival of \(k\)th trajectory, \( N \) is the total number of trajectories, and \( n_{ijk} \) is the number of the \(k\)-th-trajectory end points in the \((i,j)\) grid cell, i.e. the time spent in the \(i\)th cell by the \(k\)th trajectory. The denominator corresponds to \((i,j)\) grid cell number density. In order to reduce the uncertainty caused by cells with few trajectory end points, an arbitrary weight function \( W_{ij} \) (Polissar et al., 1999) was applied:
where $n_{ij}$ is the number of trajectory end points that fall in the $(i,j)$ grid cell.

Three-dimensional 5-day back trajectories were calculated with a 1-hour time resolution using the Hybrid Single Particle Lagrangian Integrated Trajectory Model (HYSPLIT) version 4.0 (Draxler and Hess, 1998). The end point was set at Tamanrasset ($22.79^\circ$ N, $5.53^\circ$ E), and back trajectories were calculated at ground level, 2600 and 5600 m above ground level (a.g.l.) for each day in the period 2006–2009 at 12:00 UTC with wind fields from the GDAS meteorological data set. The vertical model velocity was taken into account. The $C_{ij} \cdot W_{ij}$ values in the geographical domain longitude ($30^\circ$ W, $30^\circ$ E) and latitude ($5^\circ$ N, $50^\circ$ N) were mapped separately for the dry and the wet seasons and for back trajectories ending at the three levels mentioned above. These maps were examined to identify potential source areas or pathways of polluted air masses. The CWT method is able to distinguish major sources from moderate ones (Hsu et al., 2003).

Besides the CWT analysis, potential source contribution function (PSCF) maps (Ashbaugh et al., 1985) were also obtained in order to identify the direction and sources of air masses causing high AOD and AE values at Tamanrasset. The PSCF method estimates the conditional probability of each pixel of the geographical domain being a source location, using back trajectories arriving at the study site. The results are plotted on a map describing the spatial distribution of potential source regions. We used the same back trajectories, AOD and AE values and the arbitrary weight function, Eq. (2), for both the PSCF and CWT methods. Our resulting PSCF maps are in good agreement with those from CWT. We only show CWT results because they provided the same information on potential source locations plus additional information on the intensity of the sources, as already mentioned.

3 Results and discussion

3.1 Aerosol and precipitable water vapour characterization

3.1.1 Aerosol temporal evolution and statistics

From October 2006 to February 2009, a total of 31 800 cloud-free valid AOD observations from 790 days (92 % of the days in the period) are available. After the KCICLO correction, AOD and AE values are globally lower (around 8 and 17 %, respectively) than the time series shown by Guirado et al. (2011). The AOD, AE and FMF monthly statistics are presented in Fig. 3a, b, and c, respectively. AOD remains stable around 0.1 from November to February (absolute minimum of 0.07 in January). Conversely, AOD exceeds 0.3 from April to September reaching an absolute maximum of 0.43 in June (Fig. 3a, Table 3). High AOD variability (standard deviation > 0.30) is observed for high monthly AOD records (from April to August except May) while the lower variability (standard deviation around 0.10) coincides with the lower AOD observations (from November to January). During the period analysed, March and October act as transition months between the two main seasons. Similar results were reported by Kim et al. (2011) from a different approach. Their analysis was limited to “dust aerosol” properties by selecting data with large AOD ($\geq 0.4$) and very low AE ($\leq 0.2$). According to these criteria, non dust aerosols were identified from November to February at the Tamanrasset station.

b Dimensionless.

The annual cycle of AE and FMF is the opposite of AOD (Fig. 3). The dry season is characterized by higher AE and FMF values, reaching a maximum in January (0.69 and 0.58, respectively) and December (0.72 and 0.57, respectively) and decreasing until May (minimum of 0.15 and 0.24, respectively). A secondary maximum is observed in August with AE and FMF values of 0.44 and 0.38, respectively, associated with a decrease of the coarse mode and a slight increase of the fine mode. Such increase will be analysed in detail in Sect. 3.3.

Figure 4. Time series of (a) CBL height (metres above ground level) determined from the 12:00 UTC soundings (violet triangles) in Tamanrasset (reprinted from Guirado et al., 2011), and AERONET daily mean values of (b) PWV (mm), (c) AOD at 440 nm, and (d) AE in the range 440–870 nm (refer to legend for colour description). Solid lines correspond to 30-day moving averages. AOD and AE are dimensionless parameters.

* Mean, standard deviation, median, minimum, maximum and number of days are shown for the dry season (November–February) and for the wet season (April–September). March and October are considered transition months. 

This method was applied to AERONET level 2.0 observations which verify AOD > 0.15. This limit was selected in order to avoid errors larger than ~30% in AE and \( \delta \)AE, as advised by Gobbi et al. (2007). Basart et al. (2009) applied this graphical methodology to track and characterize

3.1.2 Aerosol classification

Guirado et al. (2011) used the graphical method proposed by Gobbi et al. (2007) to identify aerosol types at Tamanrasset. This method relies on the combined analysis of AE (440–870 nm) and its spectral curvature, represented by the Ångström exponent difference \( \delta \)AE = AE(440–670 nm) – AE(670–870 nm). These coordinates are linked to FMF (%) and aerosol fine mode size (µm) (Fig. 6) by reference points corresponding to bimodal size distributions of spherical particles which have been determined using the Mie theory on the basis of the typical refractive index of urban/industrial aerosol (\( m = 1.4 – 0.001i \)). The assumption of spherical particles is not expected to significantly impact the results (Gobbi et al., 2007). Regarding the sensitivity of the graphical method to the refractive index, the level of indetermination is of the order of ± 25% for aerosol fine mode radius \( R_f \) and ± 10% for FMF computed both for refractive index varying between \( m = 1.33 – 0.0006i \) (typical of water droplets) and \( m = 1.53 – 0.003i \) (typical of mineral dust aerosols). This method was applied to AERONET level 2.0 observations which verify AOD > 0.15. This limit was selected in order to avoid errors larger than ~30% in AE and \( \delta \)AE, as advised by Gobbi et al. (2007). Basart et al. (2009) applied this graphical methodology to track and characterize
mixtures of pollution and mineral dust, confirming the robustness of the method. Since ∼95% of AOD observations during the dry season are below 0.15 (Fig. 5a), the graphical method performed only for this period would not be representative. Thus, the same graph shown by Guirado et al. (2011), corresponding to the whole data set, was analysed.

The aerosol features at Tamanrasset (Fig. 6) are similar to those found at other arid and desert areas, such as Banizombou or Saada, reported by Basart et al. (2009). Large variations of AOD with AE almost inversely proportional to AOD are shown, thus higher extinctions are linked to larger particles. In addition, δAE is negative or slightly positive indicating a large dominance of the one-particle mode. Typical pure Saharan dust conditions (red rectangle in Fig. 6) are characterized by high-extinction values (AOD > 0.7) with AE < 0.3 and δAE < 0 that correspond to FMF < 40% and $R_E$ ∼ 0.3 µm. Aerosols presenting higher AOD (up to 0.4) than expected for AE values ranging between 0.6 and 1.1 are observed in 8.7% of the cases (green rectangle in Fig. 6). They are characterized by variable δAE, FMF and $R_f$ ranging between −0.3 and 0.2, 30 and 70%, and 0.10 and 0.20 µm, respectively. This pattern can be associated with a mixture of mineral dust and smaller particles of another origin (Basart et al., 2009) and is observed during summer. Biomass burning fine particles are discarded because they are emitted in winter time in the Sahel region. Thus, fine particles may have an urban or industrial origin as indicated by Guirado et al. (2011). This will be discussed in Sect. 3.3.

### 3.1.3 Aerosol microphysics

Multiannual monthly means of particle size distribution and volume concentration have been analysed for the period 2006–2009 (Fig. 7a, Table 5). A slight bimodality is observed with a strong predominance of coarse mode and a quite stable coarse-modal geometrical radius throughout the year with values of around 2.24 µm. This value is within the radius interval (1–3.5 µm) of maximum aerosol volume distributions reported by Ryder et al. (2013) in their comparison of aircraft campaigns performed in the central Sahara since 2000. At 2.24 µm, the coarse mode volume concentration is lower during the dry season (∼0.03 µm³ µ⁻²) in December, when minimum AOD values are recorded, and then starts to grow peaking in July (∼0.25 µm³ µ⁻²). Standard deviations are of the same order as mean values (Table 5) indicating high variability of daily measurements. The fine mode concentration shows the same seasonal pattern as the coarse mode but with values decreased by a factor of ∼10 (wet season) and ∼6 (dry season). The presence of both submicron and coarse modes throughout the year was also observed by Cuesta et al. (2008) through the analysis of in situ aerosol size distributions at Tamanrasset in 2006. They reported variability between the two modes lower than 10–15% regardless of the season.

Daily fine mode volume fraction ($V_f/V_t$) ranges between 0.03 and 0.46 (Fig. 7b) showing the dominance of the coarse mode. However, as it was discussed about FMF in Sect. 3.1.1 and 3.1.2, fine or coarse particles dominate the contribution to total AOD depending on the season. The relationship between these two fine mode quantitative parameters is shown in Fig. 7b. During the dry season, FMF and $V_f/V_t$ are roughly linearly related. During the wet season, coarse particles dominate in terms of both optical depth and volume concentration. However, few measurements meeting FMF > 0.5 and $V_f/V_t > 0.25$ are found in the wet season and most of them are linked to the fine aerosol presence analysed in Sect. 3.3.

Total effective radius follows an expected opposite seasonal pattern to AE, showing (Table 5) a maximum in May (0.86 µm), a minimum in November–December (∼0.58 µm) and a secondary minimum in August (0.61 µm). Regarding fine mode effective radius, it reaches a maximum during the dry season (∼0.16 µm in January and December) and decreases toward the lowest values in July and August (∼0.12 µm), a seasonal trend nearly the opposite of AOD. Similarly, the coarse mode effective radius shows the highest mean value in January (1.92 µm) and appears to be almost stable during the wet season ranging between 1.62 and 1.72 µm. This last result, coarse mode effective radius decreasing for higher coarse mode concentrations under desert dust conditions (Table 5), has been previously reported and linked to a practically monomodal volume particle size distribution (e.g. Prats et al., 2011, and references therein).

---

**Figure 6.** Ångström exponent difference, $\delta AE = AE(440, 675) - AE(675, 870)$, as a function of AE and AOD (refer to legend for colour and symbol description) at the Tamanrasset site (10460 observations) (reprinted from Guirado et al., 2011). Strong dust events (red rectangle) and a mixture of different aerosol types (green rectangle) are indicated. $\delta AE$, AOD and AE are dimensionless parameters.
Figure 7. (a) Monthly means of aerosol particle size distribution (\(\mu m^3\ \mu m^{-2}\)) at Tamanrasset for the period 2006–2009. Same colours are used for the dry season (blue), the wet season (orange), and the transition months (grey). (b) Scatter plot of FMF (dimensionless) and fine mode volume fraction (\(V_f/V_t\)) (dimensionless) for the dry and wet seasons (157 and 183 coincident observations, respectively).

Table 5. Monthly means of volume particle concentration (VolCon) of total, fine and coarse modes, fine mode volume fraction (\(V_f/V_t\)), and effective radius (\(R_{eff}\)) for the period October 2006–February 2009 at Tamanrasset\(^a\).

3.1.4 Aerosol optical properties

AERONET level 2.0 retrievals for single scattering albedo (SSA) and complex refractive index are limited to measurements of AOD (440 nm) > 0.4. The reason is that the accuracy of these two parameters significantly decreases under lower aerosol loading conditions: 80–100% and 0.05–0.07 for real and imaginary parts of refractive index, respectively, and 0.05 for SSA (Dubovik et al., 2000, 2002). Therefore, no information of these parameters is available in the AERONET database for the dry season at Tamanrasset. Regarding the wet season, dust optical properties (from March to October) are reported by Kim et al. (2011). To perform an analysis for the dry season, we have filtered level 1.5 data following
the same AERONET criteria but applying a smaller threshold to AOD (above 0.1, instead of 0.4, at 440 nm). A similar approach has been previously considered by other authors to investigate the role of fine aerosols on the absorption of solar radiation (e.g. Mallet et al., 2013).

The imaginary part of refractive index, the SSA, and the asymmetry parameter are relatively constant in the interval 675–1020 nm during both the dry and the wet seasons (Table 6). However, the SSA is lower at 440 nm whereas both the imaginary part (absorption) of the refractive index, as well as the asymmetry parameter, are higher at 440 nm. These spectral patterns of SSA and complex refractive index are consistent with dust-dominant conditions (e.g. Dubovik et al., 2002). For the dry season this spectral dependency is smoothed and the asymmetry parameter is slightly lower due to the decrease in the coarse mode dominance. It is worth noting that the real part of the refractive index ranges between 1.43 and 1.46 during the wet season. These values are lower than expected for dust conditions. Deviations ranging ±0.05 or more from 1.53 have been previously reported by Dubovik et al. (2002) and references therein.

3.1.5 Precipitable water vapour

The observed PWV atmospheric content shows an annual cycle quite similar to that of the CBL (Fig. 4a, b). The lowest multiannual monthly mean of PWV (Table 3) is observed in January (0.37 ± 0.16 cm) showing a low year to year variability and increases during winter and spring peaking in August (1.39 ± 0.45 cm) under the monsoon regime. PWV retrieved from radiosondes launched at 12:00 UTC has been compared (not shown) with the corresponding AERONET PWV (average of the measurements taken from 12:00 UTC to 13:00 UTC), with a good correlation (0.94) for an overall number of 610 coincident measurements. The slope of the least-squares regression line is 1.14 and the RMSE is
1.15 nm. These results are in good agreement with similar comparisons, such as that performed by Schneider et al. (2010), who reported a correlation of 0.96 between 675 AERONET and radiosonde coincident measurements (1 hour as temporal coincidence criterion) at the Izaña station.

3.2 Potential source regions

3.2.1 Concentration weighted trajectory analysis

Recently, several comprehensive reviews of potential dust sources in Northern Africa (e.g. Formenti et al., 2011; Ginoux et al., 2012) have been provided. However, our goal is to identify the potential dust sources affecting the Tamanrasset station. This study has been performed through the analysis of primary air mass pathways and their relationship with AERONET AOD and AE measurements at Tamanrasset.

CALIOP aerosol extinction profiles at 532 nm (Fig. 8c, d) have been analysed to link aerosol extinctions and air mass pathways at certain heights. The 20th percentile of the extinction in the wet season (Fig. 8d) has been selected as a threshold of pristine conditions. The features of the CBL top identified from CALIOP agree quite well with those obtained from the radiosondes. Taking into account the averaged CALIOP profiles, HYSPLIT back trajectories at several heights have been calculated for each day of the period 2007–2008. The end-point heights of the back trajectories have been selected according to the CBL top height during both the dry and the wet seasons. The three selected height levels provide information about air mass transport near the surface (ground level), at an intermediate layer (2600 m a.g.l.), which is just above the CBL top in the dry season and within the CBL during the wet season, as well as at 5600 m a.g.l., above the CBL (free troposphere) all year long (Figs. 4a, 8c, d). A first cluster analysis was performed using the k-means clustering algorithm following the Jakob and Tselioudis (2003) procedure. However, no conclusive results were found due to the variability of the cluster classification obtained for each season (dry and wet) and for each altitude. For this reason the CWT method was applied to AOD and AE parameters.

Air mass back trajectories at 2600 and 5600 m a.g.l. show a westerly component in the dry season (Fig. 9c, d), driven by the general circulation, since these levels correspond to the free troposphere over the relatively low CBL top. The dry season is characterized by low AOD and rather high AE associated with short air mass back trajectories at ground level from the first quadrant (Fig. 9a, b). Dust source regions identified as 1 and 2 in Fig. 8 might potentially affect Tamanrasset in this season. The region located in the triangle formed by Adrar des Ifoghas, Hoggar Mountains and the Air Massif (dust source 1; Fig. 8), has been previously identified (D’Almeida, 1986; Prospero, 2002; Schepanski et al., 2009; Alonso-Pérez et al., 2012) as a Saharan dust source formed by a drainage system of ephemeral rivers and streams. This source is sensitive to the effects of mesoscale winds intensified by the orography (Ginoux et al., 2012). A second potential dust source (dust source 2; Fig. 8) extends from the northwest side of the Tibesti Mountains in Chad over the eastern Libyan Desert (D’Almeida, 1986; Caquineau et al., 2002; Prospero, 2002; Ginoux et al., 2012). This source is formed by a large basin with sand seas and the northern part is marked with a chain of wadis (and associated complexes of salt/dry lakes). It is active during much of the year but it is especially intense in May–June.

In relation to AE (Fig. 9b), the highest values (smaller particles) are found around Tamanrasset. It could be the result of a mixture of desert dust and local pollution produced by cooking and heating bonfires with firewood, common in this region, which is not well dispersed by the low-level atmospheric circulation. The potential influence of biomass burning from the Sahel region to Tamanrasset during the dry season can be considered as nonexistent according to the CWT analysis.

### Table 6. Seasonal means (dimensionless) of SSA, real and imaginary parts of the refractive index (Ref. index), and asymmetry parameter (Asym.) at 440, 675, 870 and 1020 nm. Number of daily available observations (N) is also indicated.

* Corresponding standard deviations are shown in brackets.
* Level 2.0 for the wet season and level 1.5 filtered for the dry season.
* Level 2.0 for the wet and the dry season.
In the wet season, only the 5600 m a.g.l. level is over the top of a high CBL typical of summertime, showing mainly westerly trajectories (Fig. 10e). CWT analysis for AOD and AE at ground and 2600 m a.g.l. levels give similar results suggesting a well-mixed CBL in this season. AOD and AE CWT plots at ground level and 2600 m a.g.l. (Fig. 10a–d) show a curved dust pathway with relatively high values of AE (smaller particles) from northern central Libya passing over dust sources 1 and 2 as occurs in the dry season. A second curved dust pathway from the Libya–Tunisia border (Caquineau et al., 2002) (dust source 5; Fig. 8) is observed to transport larger particles (low AE) to Tamanrasset at ground level. A few air mass trajectories originate from the west passing over the large dust source 4 (Fig. 8) located in northern Mali, northern Mauritania and the western flanks of the Hoggar Mountains (Prospero, 2002; Brooks and Legrand, 2003, Alonso-Pérez et al., 2012). It is a complex distribution of dust sources with extensive dune systems that are particularly active from April to September.

Regarding one of the most significant dust sources in the world, the Bodélé Depression (Goudi and Middleton, 2001; Prospero, 2002; Brooks and Legrand, 2003) (dust source 3, Fig. 8), CWT analysis shows that it is a minor dust source affecting Tamanrasset.

### 3.2.2 Mesoscale convective system analysis

Mesoscale weather systems (dry boundary layer convection, “haboob” dust storms, nocturnal low-level jets, and southerly monsoon flow) influence dust emission, transport, and deposition over the central western Sahara (Marsham et al., 2008, 2013; Knippertz and Todd, 2010, 2012; Ashpole and Washington, 2013). During 2006, Cuesta et al. (2008) observed several summertime dust transport events over Tamanrasset associated with MCSs (mesoscale convective systems). However, MCSs cannot be well captured by global meteorological models or regional dust models (Marsham et al., 2011; Heinold et al., 2013) nor by the HYSPLIT back-trajectory parameterization. Consequently, we performed an additional analysis to identify the influence of MCSs on dust transport events over Tamanrasset.

We have analysed 21 episodes of MCSs that have been selected through comparison between observed AERONET AOD and NMMB/BSC-Dust model AOD over Tamanrasset in the period 2007–2008 (Fig. 11). The simulation of the Non-hydrostatic Multiscale Model (NMMB) Barcelona Supercomputing Center (BSC) v1 is generated using the National Center for Environmental Prediction (NCEP) reanalysis-2 (1° grid) and initial and boundary conditions from the Global Land Data Assimilation System (GLDAS). The resolution is set at 0.5° in the horizontal.

**Figure 9.** CWT maps at ground level for (a) AOD and (b) AE, and HYSPLIT back trajectories ending at (c) 2600 and (d) 5600 m a.g.l. during the dry season (from November to February). Refer to dimensionless white/red scales for colour description of AOD and AE. Tamanrasset is located at the intersection of the four quadrants.
Figure 10. CWT maps for AOD and AE at (a and b) ground level and (c and d) 2600 m a.g.l., and (e) HYSPLIT back trajectories ending at 5600 m a.g.l., during the wet season (from April to September). Refer to dimensionless white/red scales for colour description of AOD and AE. Tamanrasset is located at the intersection of the four quadrants.

and to 40 hybrid sigma-pressure model layers in the vertical. A detailed description of the model is provided by Pérez et al. (2011). The NMMB/BSC-Dust model properly reproduces dust transport associated with synoptic-scale meteorological processes observed during most of the year (Fig. 11). However, from June to September, although the AOD trend is well reproduced, the model is not capable of capturing strong and fast dust outbreaks associated with MCSs. The summertime observation-model AOD discrepancies have been used to identify the potential MCSs affecting Tamanrasset. The convective origin of each event has been evaluated by using high temporal and spatial RGB (red, green, blue) dust composites from the Meteosat Second Generation-Spinning Enhanced Visible and Infrared Imager (MSG-SEVIRI) sensor combined with European Centre for Medium-range Weather Forecasts (ECMWF) ERA-Interim reanalysis data from the IFS-Cy31r model analysis. Satellite information and meteorological data were jointly computed and visualized with McIDAS (Man computer Interactive Data Access System) software.

Once we have identified and confirmed all the MCS events impacting Tamanrasset, the Moderate Resolution Imaging Spectroradiometers (MODIS) Deep Blue 550 nm AOD retrieval has been used in a similar approach to Roberts (2014) and Roberts et al. (2014). The advantage of the MODIS Deep Blue aerosol retrieval algorithm regarding other satellite products over bright surfaces in the visible (such as deserts) is that the former employs radiances from the blue channels where the surface reflectance is relatively low (Hsu et al., 2004; 2006). The MODIS Deep Blue composite AOD...
Evidence of the arrival of fine particles to Tamanrasset during summer has been observed, in agreement with Cuesta et al. (2008) and Guirado et al. (2011). The former reported a small but non-negligible contribution of fine particles to the total AOD throughout 2006. The multiannual monthly means of AE and FMF (Fig. 3) show a local maximum in August, i.e. a decrease of the coarse mode and a slight increase of the fine mode. In addition, a mixture of fine aerosols and mineral dust has been identified mainly in July, August and September (Fig. 6). The potential sources of these fine particles are indicated by the CWT maps for AE (Fig. 10b, d) showing smaller particles arriving at Tamanrasset primarily from central Libya through a well-defined transport pathway.

Frequent mixing of particulate pollutants with desert dust in the Saharan Air Layer (SAL) was reported by Rodríguez et al. (2011). In the Izaña GAW observatory (Tenerife), they observed that dust exported from North Africa to the North Atlantic was mixed with fine nitrate and ammonium sulphate particles linked to emissions from oil refineries and power plants in Algeria, Morocco and Tunisia. The CWT maps (Fig. 10) indicate Libya and Algeria as sources of the pollutants affecting Tamanrasset. Industrial activities in these countries were identified using the Defense Meteorological Satellite Program (DMSP) night-time light product (Elvidge et al., 1997). The DMSP Operational Linescan System (OLS) has the capability to derive night-time lights of the world data sets and distinguish four primary types of lights: human settlements such as cities, towns, and villages (white), fires (red), gas flares (green), and heavily lit fishing boats (blue). Green light areas (Fig. 13) identified the location of gas flares (i.e. oil wells, refineries, or chemical plants) in Algeria and Libya.

The residence time index (Alonso-Pérez et al., 2007) accounts for the percentage of time that an air parcel remained over a horizontal grid cell defined in a geographical domain before reaching a receptor site at a predefined altitude range. This index has been used to select several case studies of fine aerosol transport to Tamanrasset from some regions of Libya and Algeria, as suggested by Guirado et al. (2011). Residence time has been computed for these predefined regions from 5-day HYSPLIT back trajectories at ground level and 2600 m a.g.l. end-point altitudes.

Nine days in July, August and September 2007 and August 2008 characterized by daily mean AE above 0.70 have been displayed in Fig. 13. Most of the trajectories both at ground level and 2600 m a.g.l. cross the western part of the northern Libyan gas flare zone and the industries located in the southwest. These trajectories are up to 32% of the time over the predefined Libyan zone. They are characterized by higher AE (≈0.90) than the average corresponding to the wet season (AE ≈ 0.28). On 29 August 2008 the back trajectory arriving at Tamanrasset at 2600 m a.g.l. shows air mass transport over the Algerian gas flares with AE ≈ 0.73 (Fig. 13). It should be noted that optical properties of anthropogenic aerosols show significant variability depending on different factors (Dubovik et al., 2002). In spite of this, available filtered level 1.5 optical properties for the nine events have been analysed (not shown). Two different patterns have been identified. On the one hand, a slight decrease in SSA and smaller differences between SSA at 440 nm and at the 675–1020 nm interval have been observed, indicating the presence of other absorbing particles apart from dust, such as organic or elemental carbon. On the other hand, several events in August 2008 show slight SSA spectral dependency and values around 0.96 (whereas the August mean value is around 0.89) indicating the presence of sulphate and/or...
nitrate aerosols. These results agree with the Rodríguez et al. (2011) observations.

4 Summary and conclusions

Tamanrasset is a strategic site for aerosol research placed in the heart of the Sahara. An aerosol characterization at this site has been provided based on more than 2 years (October 2006–February 2009) of AERONET level 2.0 and KCICLO-corrected Cimel sun photometer measurements. The top of the CBL over Tamanrasset has been characterized by both radiosonde data and CALIOP extinction vertical profiles. A strong seasonal cycle linked to the CBL is observed. The dry-cool season (November–February) is characterized by a shallow CBL, low AOD (∼0.09 at 440 nm), moderate-low AE values (∼0.62) and low PWV (∼0.51 cm). The wet-hot season (April–September) is characterized by a deep CBL, higher AOD (∼0.39 at 440 nm), low AE (∼0.28) and higher PWV (∼1.06 cm) and it is affected by strong and frequent dust storms. March and October are considered transition months. The AOD shows the same but opposite seasonal cycle to the AE and FMF. AOD remains stable around 0.1 from November to February but exceeds 0.3 from April to September, reaching an absolute maximum of 0.43 in June. The maximum AE and FMF observations are reached in December (0.72 and 0.57, respectively) and January (0.69 and 0.58, respectively), tending to decrease until May (minimum of 0.15 and 0.25, respectively). Minimum PWV is recorded in January (0.37 ± 0.16 cm) whereas maximum values are reached in August (1.39 ± 0.45 cm) linked to the monsoon regime.

Coarse mode (modal radius around 2.24 µm) prevails over the fine mode (modal radius around 0.10 µm) showing lower volume concentrations during the dry season and maxima in July. Spectral patterns of SSA and complex refractive index also indicate coarse mode dominance conditions. However, FMF and fine mode volume fraction show values corresponding to fine mode dominance in terms of optical depth, and coarse mode dominance in terms of volume concentration during the dry season. In addition, around 60% of the AOD
measurements are below 0.15, showing a cleaner atmosphere than sites located in the Sahel. The AE dry season distribution is slightly bimodal (0.4 and 0.7 modal values) and symmetrical, indicating a similar frequency for the two different particle populations (desert dust and background conditions). During the wet season AE shows two clear modes, a narrowed first mode centred at 0.15 (high dust events) and a smaller but wider mode centred at 0.4 (background conditions).

The aerosol-type characterization at Tamanrasset indicates desert mineral dust is the prevailing aerosol. Higher extinctions linked to larger particles and dominance of the one-particle mode have been identified by the observation of large variations of AOD, AE almost inversely proportional to AOD, and the Ångström exponent difference ($\delta_{AE}$), negative or slightly positive. Moreover, typical pure Saharan dust conditions have been observed, i.e. high-extinction values (AOD > 0.7) with AE < 0.3 and $\delta_{AE}$ < 0 corresponding to FMF < 40% and fine mode radius ($R_f$) of around 0.3 µm. However, an anthropogenic fine mode contribution has been found mixed with mineral dust (8.7% of total cases), i.e. AOD of up to 0.4 for AE values ranging between 0.6 and 1.1 and $\delta_{AE}$, FMF and $R_f$ between −0.3 and 0.2, 30 and 70%, and 0.10 and 0.20 µm, respectively.

Potential sources of the air masses arriving at Tamanrasset have been identified: the triangle formed by Adrar des Ifoghas, Hoggar Mountains and Air Massif; a complex distribution of dust sources including northern Mali, northern Mauritania and the western flanks of the Hoggar Mountains; and the eastern Libyan Desert. However, the Bodélé Depression has been found to be a minor potential source at Tamanrasset. Dust uplift sources associated with summertime MCS events located south of Tamanrasset have been also identified.

Evidence of the arrival of fine particles to Tamanrasset during summer has been detected and nine events of polluted air masses coming from urban/industrial areas in Libya and Algeria have been shown.

Acknowledgements. The AERONET sun photometer at Tamanrasset has been calibrated within AERONET-EUROPE TNA supported by the PHOTONS and RIMA networks and partially financed by the European Community – Research Infrastructure Action under the Seventh Framework Programme (FP7/2007-2013) “Capacities” specific programme for Integrating Activities, ACTRIS grant agreement no. 262254. The authors gratefully acknowledge the NOAA Air Resources Laboratory (ARL) for the provision of the HYSPLIT transport and dispersion model and READY website (http://ready.arl.noaa.gov) used in this publication. We also thank Google Earth™. Financial support from the Spanish MINECO (projects CGL2011-23413, CGL2012-33576 and CGL2012-37505) is also gratefully acknowledged. We are particularly grateful to the Tamanrasset Global Atmospheric Watch (GAW) station’s staff (l’Office National de la Météorologie, Algeria) for supporting the measurement program. J. M. Baldasano and S. Basart acknowledge the Supercomputación y eCiencia project (CSD2007-0050) from the Consolider-Ingenio 2010 and Severo Ochoa (SEV-2011-00067) programs of the Spanish Government. We also acknowledge our colleague Dr. Celia Milford for improving the English language of the manuscript.
