Abstract. We use a global aerosol microphysics model in combination with an offline radiative transfer model to quantify the radiative effect of biogenic secondary organic aerosol (SOA) in the present-day atmosphere. Through its role in particle growth and ageing, the presence of biogenic SOA increases the global annual mean concentration of cloud condensation nuclei (CCN; at 0.2 % supersaturation) by 3.6–21.1 %, depending upon the yield of SOA production from biogenic volatile organic compounds (BVOCs), and the nature and treatment of concurrent primary carbonaceous emissions. This increase in CCN causes a rise in global annual mean cloud droplet number concentration (CDNC) of 1.9–5.2 %, and a global mean first aerosol indirect effect (AIE) of between +0.01 W m⁻² and −0.12 W m⁻². The radiative impact of biogenic SOA is far greater when biogenic oxidation products also contribute to the very early stages of new particle formation; using two organically mediated mechanisms for new particle formation, we simulate global annual mean cloud droplet number concentration (CDNC) of 1.9–5.2 %, and a global mean first aerosol indirect effect (AIE) of between +0.01 W m⁻² and −0.12 W m⁻². The radiative impact of biogenic SOA is far greater when biogenic oxidation products also contribute to the very early stages of new particle formation: using two organically mediated mechanisms for new particle formation, we simulate global annual mean first AIEs of −0.22 W m⁻² and −0.77 W m⁻². The inclusion of biogenic SOA substantially improves the simulated seasonal cycle in the concentration of CCN-sized particles observed at three forested sites. The best correlation is found when the organically mediated nucleation mechanisms are applied, suggesting that the first AIE of biogenic SOA could be as large as −0.77 W m⁻². The radiative impact of SOA is sensitive to the presence of anthropogenic emissions. Lower background aerosol concentrations simulated with anthropogenic emissions from 1750 give rise to a greater fractional CCN increase and a more substantial first AIE from biogenic SOA. Consequently, the anthropogenic indirect radiative forcing between 1750 and the present day is sensitive to assumptions about the amount and role of biogenic SOA. We also calculate an annual global mean direct radiative effect of between −0.08 W m⁻² and −0.78 W m⁻² in the present day, with uncertainty in the amount of SOA produced from the oxidation of BVOCs accounting for most of this range.

1 Introduction

Vegetation emits biogenic volatile organic compounds (BVOCs), such as monoterpenes (C₁₀H₁₆) and isoprene (C₅H₈), into the atmosphere (Guenther et al., 1995). Once emitted, BVOCs oxidise to yield a range of lower volatility oxidation products that can partition into the aerosol phase, forming secondary organic aerosol (SOA) (Kavouras et al., 1998; O’Dowd et al., 2002; Kanakidou et al., 2005; Jimenez et al., 2009). The oxidation products of monoterpenes and isoprene have been observed in both ambient aerosol (e.g. Kavouras et al., 1999; Yu et al., 1999b; Claeyss et al., 2004; Robinson et al., 2011) and in laboratory chamber experiments (e.g. Hatakeyama et al., 1989; Edney et al., 2005; Kroll et al., 2005, 2006). Over Scandinavia, parcels of air have
been found to contain an aerosol mass that is proportional to the length of time the air has spent over forested land (Tunved et al., 2006, 2008), suggesting an important contribution to aerosol from BVOC emissions.

Whilst organic aerosol has been shown to dominate the mass of fine aerosol over much of the world (Zhang et al., 2007; Jimenez et al., 2009), the climate effects of biogenic SOA are not well understood. The presence of SOA can influence the Earth’s radiative balance by contributing to the absorption and scattering of radiation (the direct effect) and by altering the properties of clouds (indirect effects) (Forster et al., 2007). Incoming solar radiation peaks at wavelengths between 380 nm and 750 nm, so processes that aid in the growth of particles up to these sizes, such as the condensation of secondary organic material, will have a direct radiative effect (DRE). The annual global DRE from biogenic SOA has been previously estimated at between $-0.01 \, \text{W m}^{-2}$ (all sky; Goto et al., 2008) and $-0.29 \, \text{W m}^{-2}$ (clear sky; O’Donnell et al., 2011), but regional effects may be much larger, e.g. up to $-1 \, \text{W m}^{-2}$ over tropical forest regions (Rap et al., 2013) and a Northern Hemisphere (NH) summertime mean of between $-0.37 \, \text{W m}^{-2}$ and $-0.74 \, \text{W m}^{-2}$ over boreal regions (Lihavainen et al., 2009).

The first aerosol indirect effect (AIE), or cloud albedo-effect, describes the radiative perturbation resulting from a change to the number concentration of cloud droplets when a fixed cloud water content is assumed (Twomey, 1977). This change is governed by the number of particles in the atmosphere that are able to act as cloud condensation nuclei (CCN), as determined by their size and chemical composition (Penner et al., 2001; Dusek et al., 2006). SOA formed from the oxidation products of isoprene and monoterpenes has been shown to be CCN-active under atmospherically relevant conditions, with a hygroscopicity parameter close to 0.1 (Duplissy et al., 2008; Engelhart et al., 2008, 2011). The presence of SOA can affect CCN number concentrations in several ways. Organic compounds are known to aid in the growth of newly formed particles ($\sim 1–2 \, \text{nm}$ diameter) to observable sizes ($> 3 \, \text{nm}$ diameter; Boy et al., 2003; Kulmala et al., 2004; Verheggen et al., 2007; Laaksonen et al., 2008; Pierce et al., 2011; Yli-Juuti et al., 2011; Riccobono et al., 2012) and even further to a CCN-active size ($> 70 \, \text{nm}$ diameter; Riipinen et al., 2011, 2012; Pierce et al., 2012; Paasonen et al., 2013). Additionally, the oxidation products of terpenes may play a role in the initial stages of particle formation via stabilisation of the critical nucleus (Fan et al., 2006; Zhang et al., 2009; Metzger et al., 2010; Paasonen et al., 2010; Kulmala et al., 2013). By contrast, both laboratory (Kiendler-Scharr et al., 2009) and field experiments (Kanawade et al., 2011) indicate that isoprene emissions may act to suppress new particle formation in the presence of high isoprene to monoterpene emission ratios, although the mechanism through which this process operates is not known.

Several studies suggest a large first AIE from biogenic SOA over the boreal forests at high northern latitudes. Using a global aerosol microphysics model, Spracklen et al. (2008a) simulated a doubling of regional summertime CCN concentrations as a result of monoterpane emissions, and a subsequent regional first AIE of between $-1.8$ and $-6.7 \, \text{W m}^{-2}$ of boreal forest. Using measurements made at Pallas in Finland, Lihavainen et al. (2009) estimated a local summertime first AIE of between $-3.2$ and $-6.4 \, \text{W m}^{-2}$ over the boreal forest region. A stronger annual first AIE (locally between $-5$ and $-14 \, \text{W m}^{-2}$) was calculated by Kurten et al. (2003) using measurements taken at Hyytiälä in southern Finland. Globally, the AIE is weaker, and previous estimates range from negative to positive values. Rap et al. (2013) estimate a global annual mean first AIE of $-0.02 \, \text{W m}^{-2}$ due to monoterpane SOA, and Goto et al. (2008) simulate an AIE (including cloud lifetime and semi-direct effects) of $-0.19 \, \text{W m}^{-2}$. However, Goto et al. (2008) use an aerosol model that treats aerosol mass only, which is not ideal when examining processes that will influence the number size distribution (Bellouin et al., 2013). By contrast, O’Donnell et al. (2011) simulate a decrease in global mean CCN concentration and therefore a positive AIE of $+0.23 \, \text{W m}^{-2}$ for the emission of both biogenic and anthropogenic volatile organic compounds (VOCs), potentially due to their differing microphysical treatment of SOA.

The aim of this study is to quantify the radiative effects of biogenic SOA in the present-day atmosphere and examine the sensitivity to several important processes and parameters. We simulate changes in the global aerosol distribution resulting from the emission of BVOCs and calculate the DRE and first AIE. In order to examine the influence of present-day anthropogenic emissions on the radiative effect of biogenic SOA, we also calculate the radiative effect of SOA in a pre-industrial atmosphere.

2 Method

2.1 Model description

The Global Model of Aerosol Processes (GLOMAP; Spracklen et al., 2005a) is an extension to the TOMCAT global 3-D chemical transport model (Chipperfield, 2006). Here we use GLOMAP-mode (version 6), in which information about aerosol component masses and number concentrations is carried in five log-normal size modes (Mann et al., 2010, 2012): four hydrophilic (nucleation, Aitken, accumulation and coarse), and a non-hydrophilic Aitken mode. Material in the particle phase is classified into four components: sulphate (SU), black carbon (BC), particulate organic matter (POM) and sea salt (SS). GLOMAP includes representations of nucleation, particle growth via coagulation, condensation and cloud processing, wet and dry deposition, and, in- and below-cloud scavenging.

The model has a horizontal resolution of $2.8^\circ \times 2.8^\circ$ with $31 \sigma$-pressure levels from the surface to 10 hPa. Meteorology
is obtained from European Centre for Medium-Range Weather Forecasts (ECMWF) reanalyses at six-hourly intervals and cloud fields from the International Satellite Cloud Climatology Project (ISCCP) archive (Rossow and Schiffer, 1999). All simulations are performed for the year 2000, with six months’ spin-up from zero initial aerosol.

2.1.1 Gas-phase emissions and chemistry

Monthly emissions of monoterpenes and isoprene are taken from the Global Emissions Initiative (GEIA) database (Guenther et al., 1995), which gives total emissions of 127 and 503 Tg(C) a\(^{-1}\) respectively. Considerable variability is observed in the yield of SOA generated by BVOC oxidation (e.g. Yu et al., 1999a; Kroll et al., 2006; Shilling et al., 2009). Here we generate SOA at fixed molar yields of 13 % and 3 % for the oxidation of monoterpenes and isoprene respectively; monoterpenes are prescribed the reaction characteristics of \(\alpha\)-pinene and oxidation reactions proceed at the rates given in Table 1. The use of a 13 % molar yield for the production of monoterpane SOA follows the approach of Spracklen et al. (2006), which was based on Tunved et al. (2004a). Tunved et al. (2006) revised this estimate downwards to an apparent mass yield of between 5 and 10 %, suggesting that the atmospheric yield may be lower than the 13 % molar yield (equivalent to a 14.3 % mass yield) used in GLOMAP. The 3 % molar yield (equivalent to a 3.3 % mass yield) for the production of isoprene SOA is based on the yields obtained by Kroll et al. (2005, 2006) over a range of experimental conditions (0.9–5.5 % mass yield).

The global production of biogenic SOA is poorly constrained, with estimates ranging between 12 Tg(SOA) a\(^{-1}\) and 1820 Tg(SOA) a\(^{-1}\) (Griffin et al., 1999; Kanakidou et al., 2005; Goldstein and Galbally, 2007; Heal et al., 2010, 2011; Spracklen et al., 2011b). Using molar yields of 13 % and 3 % (for monoterpenes and isoprene respectively) produces approximately 37 Tg(SOA) a\(^{-1}\) in our model, which is towards the lower end of current estimates. Consequently, it may be the case that the yields applied here are too low (i.e. do not produce enough SOA), or too high (Tunved et al., 2006). We explore this uncertainty by varying the SOA production yield in a series of sensitivity experiments.

2.1.2 Primary particulate emissions

Annual mean emissions of BC and POM from fossil and biofuel combustion are based on energy data from 1996 and taken from Bond et al. (2004); monthly wildfire emissions for the year 2000 are from the Global Fire Emissions Database (GFED) inventory (van der Werf et al., 2004). In a sensitivity study we use wildfire and anthropogenic emissions from the year 1750, compiled for the AeroCom initiative (Dentener et al., 2006). The emission of primary sea-salt aerosol is parameterised according to Gong (2003).

2.1.3 New particle formation

Since new particle formation has been shown to strongly affect CCN concentrations (Spracklen et al., 2008b) and simulated aerosol indirect radiative effects (Bellouin et al., 2013), we quantify the impact of BVOC emissions using four nucleation mechanisms. In all experiments we include a parameterisation to represent the binary homogeneous nucleation (BHN) of sulphuric acid and water (Kulmala et al., 1998a) which occurs mainly in the free troposphere (e.g. Spracklen et al., 2005b). New particle formation rates in the boundary
layer cannot be adequately explained by BHN alone, so we examine the impact of BVOC emissions when three additional parameterisations for new particle formation are applied in the boundary layer, in combination with BHN. The first parameterisation is an empirically derived mechanism for the activation (ACT) of sulphuric acid clusters in the boundary layer based on the work of Kulmala et al. (2006). With this approach, molecular clusters activate at a rate \( J^*_\text{Act} \) proportional to the gas-phase concentration of sulphuric acid (Eq. 1). The coefficient \( A \) represents the complexity of the activation process and may be a function of several parameters such as temperature and the concentration of other species (potentially organics). Here we use a value for \( A \) of 2 × 10^{-6} s^{-1} (as determined empirically by Sihto et al., 2006) and restrict this mechanism to the boundary layer, allowing BHN to proceed at higher altitudes.

\[
J^*_\text{Act} = A [H_2SO_4] \tag{1}
\]

The final two parameterisations, Org1 (Eq. 2) and Org2 (Eq. 3) are implemented using the particle formation rates described by Metzger et al. (2010) and Paasonen et al. (2010) respectively \((k = 5 \times 10^{-13} \text{ s}^{-1}, k_1 = 1.1 \times 10^{-14} \text{ s}^{-1}, k_2 = 3.2 \times 10^{-14} \text{ s}^{-1})\). In smog chamber experiments, Metzger et al. (2010) found that particle formation rates were proportional to the product of the gas-phase concentrations of sulphuric acid and low volatility products from the photo-oxidation of an SOA precursor species (1,3,5-trimethylbenzene). They also found that sub-3 nm particle growth rates were too high to be explained by sulphuric acid vapour alone, and proposed that organic oxidation products were also required to explain the observations. Paasonen et al. (2010) found a good correlation against a wide observational data set when the particle formation rate combined a term based on the product of the concentrations of sulphuric acid and an organic molecule with a kinetic nucleation term proportional to the square of sulphuric acid concentration. When implementing these two organically mediated nucleation mechanisms, we include only the product from monoterpene oxidation as the organic oxidation product, since the role of isoprene oxidation products in new particle formation remains unclear. Our experiments therefore apply these two nucleation rate parameterisations (Eqs. 2 and 3) throughout the atmosphere, using the first stage product from monoterpene oxidation as the condensable organic species, “org”:

\[
J^*_{\text{Org1}} = k [H_2SO_4] [\text{org}], \tag{2} \\
J^*_{\text{Org2}} = k_1 [H_2SO_4]^2 + k_2 [H_2SO_4] [\text{org}]. \tag{3}
\]

As the focus of this study is to investigate the role of biogenic SOA, we do not consider ternary homogeneous nucleation, but, as has been shown recently by Almeida et al. (2013), ternary nucleation involving amines may be an important process in the boundary layer.

The growth of newly formed clusters is not simulated explicitly, but the production rate \( J_m \) of particles at a measurable size \((\text{taken as } d_m = 3 \text{ nm})\) is calculated using the approximation of Kerminen and Kulmala (2002), as given in Eq. (4). The dry cluster diameter, \( d^* \), is taken as 0.8 nm for \( J^*_\text{Act} \), 1.5 nm for \( J^*_{\text{Org1}} \) (Metzger et al., 2010), and 2 nm for \( J^*_{\text{Org2}} \) (Paasonen et al., 2010).

\[
J_m = J^* \exp \left[ 0.23 \left( \frac{1}{d_m} - \frac{1}{d^*} \right) \text{CS}' \right] \tag{4}
\]

This production rate accounts for scavenging by larger particles, and allows growth of nucleated clusters up to \( d_m \) at a constant growth rate, \( GR \), proportional to the gas-phase concentration of sulphuric acid. The reduced condensation sink, \( \text{CS}' \), is calculated by integrating over the aerosol size modes following Kulmala et al. (2001b).

### 2.2 Model experiments

To examine the extent to which the simulated climate impacts of biogenic SOA are sensitive to our model’s treatment of aerosol processes, we completed the series of model experiments described in Table 2. These simulations explore the impact of uncertainty in the SOA yield from BVOC oxidation, the role of organic oxidation products in new particle formation, and the interaction between SOA and primary carbonaceous aerosol emissions. To account for the uncertain yield of SOA produced by the oxidation of BVOCs, we varied the SOA mass yields by different factors (experiments 5 to 7), resulting in a global annual production of between 18.5 Tg(SOA) a^{-1} and 185 Tg(SOA) a^{-1}.

The global annual production of SOA from these yield experiments is detailed in Table 2 and all lie within the wide range of previous estimates (Griffin et al., 1999; Kanakidou et al., 2005; Goldstein and Galbally, 2007; Heald et al., 2010, 2011; Spracklen et al., 2011b).

In GLOMAP, the simulated aerosol size distributions, and therefore the CCN concentrations, are sensitive to the treatment of primary anthropogenic emissions (Reddington et al., 2011; Spracklen et al., 2011a), in particular the emission characteristics of primary carbonaceous aerosol. Here, we emit primary carbonaceous particles with the distribution characteristics described by Stier et al. (2005) in our standard simulations, i.e. number median diameter \( D_{nf} = 60 \text{ nm} \) and \( D_{bf} = 150 \text{ nm} \), standard deviation \( \sigma_{nf} = 1.59 \) and \( \sigma_{bf} = 1.59 \) (where ff refers to fossil fuel and bf to biofuel/wildfire). We explore the sensitivity to this choice with an additional set of simulations (experiments 11 and 12) using smaller emission sizes \( (D_{nf} = 30 \text{ nm}, D_{bf} = 80 \text{ nm}) \), but wider distributions \( (\sigma_{nf} = 1.8, \sigma_{bf} = 1.8) \) recommended by AeroCom (Dentener et al., 2006).

The process of physical ageing, by which non-hydrophilic particles become hydrophilic via condensation of soluble material, is poorly understood (Kanakidou et al., 2005). In GLOMAP, primary BC/POM particles are emitted into a
Table 2. Summary of model simulations and global annual mean changes to N\textsubscript{3} (number concentration of particles > 3 nm diameter) at the surface, surface level CCN (0.2 % supersaturation) concentration, and CDNC at cloud height (approximately 900 hPa), with subsequent all-sky DRE and first AIE (highlighted in bold text), relative to an equivalent control simulation including no BVOC emission (Mon = monoterpenes, Iso = isoprene).

\*Experiments 3–7 were repeated with 1750 emissions of BC, POM and SO\textsubscript{2} to examine the effect of altering the yield of SOA production in a pre-industrial atmosphere.
non-hydrophilic distribution and transferred to an internally mixed hydrophilic distribution after the condensation of a specific amount of condensable material. Our standard simulations assume that ten monolayers of condensable material (secondary organics or sulphuric acid) are required to coat an insoluble particle sufficiently for it to become soluble. To examine the importance of this process and its representation with respect to the impact of biogenic SOA, we perform one simulation in which physical ageing does not occur as a result of the condensation of secondary organics (experiment 8), and others in which only one soluble monolayer is required (experiments 9 and 10).

The sensitivities examined here are not intended to provide an exhaustive assessment of the uncertainty associated with the radiative impact of biogenic SOA, but to highlight the importance of several key parameters in determining the direct and indirect effects. A more thorough assessment of sensitivities and feedbacks would require an emulator-style approach (e.g. Lee et al., 2012) to model the entire parameter space.

2.3 Calculation of CCN concentrations

CCN concentrations were calculated offline, from monthly mean aerosol tracers, using the approach of Petters and Kreidenweis (2007). A hygroscopicity parameter ($\kappa$) is assigned to each component; a multi-component $\kappa_{\text{multi}}$ is then obtained by weighting the individual $\kappa$ values by the volume fraction of each component. We assign the following individual hygroscopicity parameters: sulphate (0.61, assuming ammonium sulphate), sea salt (1.28), black carbon (0.0), and particulate organic matter (0.1). Whilst there is uncertainty associated with the hygroscopicity parameter for organic material in the atmosphere due to the wide range of solubilities observed, $\kappa$ values close to 0.1 have been reported for secondary organic components (Engelhart et al., 2008, 2011; Gunthe et al., 2009; Dusek et al., 2010; King et al., 2010), and the entire organic fraction (Wang et al., 2008; Chang et al., 2010). We calculate CCN concentrations at a supersaturation of 0.2%, which is equivalent to an activation dry diameter of approximately 80 nm (assuming a composition of pure ammonium sulphate). We assume that BC/POM particles in the non-hydrophilic distribution do not act as CCN.

2.4 Cloud droplet number concentration

Cloud droplet number concentrations (CDNC) are calculated using the parameterisation of Nenes and Seinfeld (2003), as updated by Fountoukis and Nenes (2005) and Barahona et al. (2010). The monthly mean aerosol size distribution is converted to a supersaturation distribution from which the number of activated particles can be determined for the diagnosed maximum supersaturation ($S_{\text{max}}$). The $S_{\text{max}}$ of an ascending cloud parcel represents the competition between increasing water vapour saturation with decreasing temperature, and the loss of water vapour through condensation onto activated particles. As such, $S_{\text{max}}$ depends upon the aerosol population and should be diagnosed rather than prescribed uniformly, as discussed by Pringle et al. (2009). Here, CDNC are calculated with a prescribed constant updraught velocity of 0.15 m s$^{-1}$ over sea and 0.3 m s$^{-1}$ over land, consistent with those commonly observed for low-level stratus and stratocumulus clouds (Guibert et al., 2003; Peng et al., 2005; Pringle et al., 2012).

2.5 Radiative effects

The DRE and first AIE of biogenic SOA are determined using the offline radiative transfer model of Edwards and Slingo (1996) with nine bands in the longwave and six bands in the shortwave. We use a monthly mean climatology based on ECMWF reanalysis data, together with cloud fields from the ISCCP-D2 archive (Rossow and Schiffer, 1999) for the year 2000. Sensitivity of direct and first indirect radiative effects to the cloud climatology used (i.e. single year versus multi-annual mean) was examined in Rap et al. (2013) and found to be negligible for a range of natural aerosol sources, including monoterpene-derived SOA.

To determine the DRE, following the methodology described in Rap et al. (2013), the radiative transfer model is used to calculate the difference in net top-of-atmosphere (SW + LW) all-sky radiative flux between experiments including SOA and the equivalent experiments without SOA. Aerosol scattering and absorption coefficients together with asymmetry parameters are calculated for each aerosol size mode and spectral band, as described in Bellouin et al. (2013).

The first AIE is calculated as in Schmidt et al. (2012); a uniform control cloud droplet effective radius ($r_{e1}$) of 10 $\mu$m is assumed to maintain consistency with the ISCCP cloud data, and for each perturbation experiment the effective radius ($r_{e2}$) is calculated as in Eq. (5), from cloud droplet number fields CDNC$_1$ and CDNC$_2$ respectively. For each experiment, CDNC$_1$ represents the simulation including SOA, and CDNC$_2$ represents the simulation with no SOA.

$$r_{e2} = r_{e1} \times \left[ \frac{\text{CDNC}_1}{\text{CDNC}_2} \right]^{\frac{3}{2}}$$

The first AIE of biogenic SOA is then calculated by comparing net (SW + LW) radiative fluxes (using the varying $r_{e2}$ values derived for each perturbation experiment), to those of the control simulation with fixed $r_{e1}$. In these offline experiments, we do not calculate the second aerosol indirect (cloud lifetime) effect.
3 Results

3.1 Changes to total particle and CCN number concentrations

Table 2 reports the impact of biogenic SOA on simulated aerosol properties. SOA increases the condensation sink, potentially suppressing new particle formation and growth. This results in the global annual mean total particle (N$_3$; greater than 3 nm dry diameter) concentration being reduced by 7.9% when monoterpenes emissions are included with activation boundary layer nucleation (experiment 2) and by 0.4% when BHN is the only new particle formation mechanism (experiment 14). By contrast, when organics contribute directly to nucleation (experiments 16 and 18), a global annual mean increase in N$_3$ of between 22.0% and 142.0% is simulated. In these simulations, the additional nucleation caused by the presence of organics dominates the moderate reduction in N$_3$ due to the enhanced condensation sink.

In all the model configurations examined here, biogenic SOA increases the simulated global annual mean surface CCN concentration, with the relative enhancement ranging between 3.6% and 45.2% (Table 2). The spatial distribution of changes to CCN concentration (Fig. 1) does not simply match the distribution of BVOC emissions due to the diverse range of processes controlling the aerosol size distribution and CCN number. For the ACT simulation shown in Fig. 1, biogenic SOA (from monoterpenes and isoprene) increases annual mean CCN concentrations by up to 120% over the Amazon, whilst reducing annual mean CCN concentrations by up to 8% over some tropical oceans.

The largest increases in absolute CCN concentration are simulated in regions experiencing high levels of primary particulate emissions, particularly tropical regions affected by biomass burning. This suggests an important relationship between SOA and the presence of primary particles. In our model, primary carbonaceous aerosol from fossil fuel combustion and wildfire is initially non-hydrophilic, being emitted into the Aitken insoluble mode. Condensation of soluble gas-phase species moves these particles into the hydrophilic Aitken mode, where they are able to act as CCN. Without this physical ageing by SOA, the global annual mean increase in CCN concentration is reduced to 3.6% (experiment 8), compared to 12.8% in the equivalent standard run (experiment 4). When the physical ageing requires only one monolayer of soluble material (experiment 10), the global mean increase in CCN number concentration is reduced to 8.9% because carbonaceous particles are more efficiently coated and transferred to the hydrophilic distribution by sulphuric acid, such that CCN concentrations are less sensitive to the presence of organics. Using a smaller emission size for primary carbonaceous aerosol (experiment 12) increases the global annual mean change to surface CCN concentrations when biogenic SOA is included to 17.5%. A smaller emission size increases the number of primary particles emitted per mass of carbonaceous material, thereby providing more non-hydrophilic particles ready to be aged to the hydrophilic modes where they are able to act as CCN. Additionally, the lower surface area of smaller particles allows a faster rate of ageing by a given amount of SOA.

At tropical latitudes (30°N to 30°S), high year-round emissions of both isoprene (87% of global total emissions) and monoterpenes (78% of total) result in large increases to CCN concentrations (Fig. 1) throughout the seasonal cycle (Fig. 2, left). At 30°N to 90°N, increases in CCN are largest during the summer, with small increases simulated in winter months when emissions of BVOC are low. Over the high-latitude boreal forests, monoterpane emissions are responsible for the majority of the CCN increase (Fig. 2, left), owing to their higher emission rate compared to isoprene. In the
Southern Hemisphere (SH; specifically 30°–90° S), absolute CCN changes are small throughout the year due to low emissions of BVOC at these latitudes (Fig. 1, left and Fig. 2, left). However, relatively low absolute changes result in substantial fractional changes, particularly over the oceans (Fig. 1, right) due to low background CCN number concentration.

Within 30° either side of the Equator, BVOC emissions from the GEIA inventory (Guenther et al., 1995) are slightly higher during the respective wet seasons (April–September in northern tropics; October–March in southern tropics), but as shown in Fig. 2 (right), the largest absolute increase in CCN concentration occurs during the dry seasons when primary carbonaceous emissions from wildfires are highest. The importance of ageing is confirmed by much lower CCN increase simulated when secondary organic material does not transfer hydrophobic particles to the hydrophilic distribution (dotted lines in Fig. 2, right). At high northern latitudes, the process of ageing also contributes to the summertime CCN increase (Fig. 2, right), but a more substantial contribution here comes from the growth of smaller particles to CCN-active sizes via condensation of organic material.

BVOC emissions result in reductions in simulated CCN concentrations over some regions (Fig. 1). Reductions in CCN are driven by several different processes. Firstly, the presence of biogenic SOA enhances the condensation sink over continental regions, resulting in increased condensation of sulphuric acid to existing particles. This can lower sulphuric acid concentrations in the upper troposphere, subsequently reducing binary homogeneous nucleation and the number of particles entrained into the boundary layer. This entrainment of particles formed in the upper troposphere makes the largest contribution to surface CCN concentrations over the subtropical oceans (Merikanto et al., 2009). Additionally, in regions with particularly high SO₂ emission (e.g. eastern Asia; Fig. 1), and therefore high H₂SO₄ concentrations, the enhanced condensation sink may also suppress new particle formation and growth as a route for CCN generation in the boundary layer, reducing CCN concentrations in the presence of biogenic SOA.

Secondly, the presence of biogenic SOA allows non-hydrophilic particles to be aged (i.e. transferred to the hydrophilic distribution) and enhances their growth up to the size at which they may be nucleation scavenged (taken here as particles with dry diameter > 206 nm). In the absence of SOA, particle growth may only proceed via coagulation and condensation of sulphuric acid. Therefore in the presence of SOA, particles grow more quickly to a size where they may be removed from the atmosphere by wet deposition.

Monoterpene emissions contribute a greater increase to global annual mean CCN concentration than isoprene emissions (experiments 2 and 3; Table 2). This occurs partly because a greater amount of SOA is generated from their oxidation, despite total annual monoterpene emissions in the Guenther et al. (1995) data set being a factor of four lower than those for isoprene, but may also be due to the spatial distribution of emissions and relative proximity to sources of fine particles that require growth to reach CCN sizes (e.g. carbonaceous particles from fossil fuel combustion). As indicated in Fig. 2 (left), the contributions of each BVOC are not additive: monoterpene and isoprene SOA increase CCN concentrations by approximately 10.4 % and 8.5 % respectively, whereas the combined emission results in only 12.8 % increase, suggesting a saturation of the global CCN response. This is confirmed by the variation in CCN change observed for experiments 4 to 7, where a factor of 5 increase in the SOA production yield results in less than a doubling of absolute and fractional CCN changes. This occurs because the generation of additional CCN (via condensation of secondary
organic material) becomes limited by the enhanced condensation sink (due to larger particle sizes) and consequent suppression of new particle formation.

### 3.2 Sensitivity to new particle formation

The simulated contribution of SOA to global mean CCN concentrations depends strongly on the nucleation mechanism used in the model. Inclusion of an empirically derived particle activation mechanism within the boundary layer (i.e. ACT, Eq. 1) results in a greater absolute global annual mean change in CCN concentration due to monoterpene SOA (+23.5 cm⁻³; experiment 2), when compared to the equivalent simulation using only BHN (+20.3 cm⁻³; experiment 14). This occurs because particles formed by the activation of H₂SO₄ clusters in the boundary layer are able to grow to CCN-active sizes by the condensation of organic oxidation products and is particularly evident between 40 and 60° N (Fig. 3, left) where there is a strong contribution to total particle numbers from nucleation within the boundary layer (Merikanto et al., 2009). However, a similar annual global mean fractional CCN change (+10.4 %) due to monoterpene SOA is simulated in each case, owing to the higher background CCN concentration when the ACT mechanism is used.

When monoterpene oxidation products are allowed to participate in the very early stages of new particle formation (experiments 15 to 18), the contribution of biogenic SOA to CCN concentrations is substantially greater, increasing the global annual mean by 15.5 % for Org2 and 45.2 % for Org1. The large increase in CCN concentrations when the Org1 mechanism is used can be attributed to the fact that in the absence of BVOC emissions, new particle formation in the boundary layer does not occur. In a test simulation, the value for $d^*$ in the Org1 experiments was reduced from 1.5 nm to 0.8 nm (to match ACT but not intended to represent a real scenario). This reduced the percentage increase in global annual mean CCN concentration (upon inclusion of biogenic SOA) from 45.2 % to 35.9 %, indicating that most of the enhancement in CCN concentration comes from the inclusion of organics in the nucleation rate itself, but some is due to the increased survival probability of newly formed particles associated with assuming a larger value for $d^*$. With this mechanism, the peak annual mean absolute increase in CCN concentration occurs at approximately 40° N (Fig. 3, left) due to large CCN increases simulated over south-east USA, Europe and China, regions of high monoterpene emission during the NH summer. Substantial fractional increases (over 100 %) are simulated in regions where high monoterpene emissions combine with low background aerosol number concentrations, such as the boreal regions of northern Russia and Canada (Fig. 3, right).

### 4 Comparison to observations

The simulated seasonal cycle in the number concentration of particles with dry diameter greater than 80 nm ($N_{80}$) was compared against multi-annual monthly mean observations at three forested sites: Hyytiälä, Finland from 1996 to 2006 (Kulmala et al., 1998b, 2001a), Pallas, Finland from 2000 to 2011 (Hatakka et al., 2003; Komppula et al., 2003), and Aspvreten, Sweden from 2005 to 2007 (Tunved et al., 2004b). These locations were chosen since they are relatively remote from anthropogenic aerosol sources and are in regions with substantial BVOC emissions. We chose to evaluate $N_{80}$ concentrations since these match particles of CCN relevant size. Although $N_{80}$ does not take into account the composition or solubility of the particles, long-term observations of CCN are not yet available at locations suitable for this study. Observations were taken from the EBAS database (available at http://ebas.nilu.no) and monthly mean model values are bilinearly interpolated to each location.

Table 3 gives, for a selection of our experiments, the correlation coefficient ($R$) between simulated and observed monthly mean $N_{80}$ concentrations at each site, and Fig. 4...
shows the observed and simulated seasonal cycle at Hyytiälä and Pallas. A pronounced seasonal cycle in N$_{80}$ is observed at these locations, with summertime (JJA) concentrations a factor of two greater than wintertime (DJF) concentrations. Without biogenic SOA, summertime N$_{80}$ concentrations are under-predicted (dotted lines in Fig. 4) and simulations do not capture the seasonal cycle; the maximum correlation coefficient at Hyytiälä is 0.37 (Org2), 0.16 at Aspvreten (Org2), and 0.14 at Pallas (Org2). The inclusion of biogenic SOA improves the correlation between simulated and observed values for each set of simulations at all three locations, primarily by increasing summertime N$_{80}$ concentrations.

When the ACT mechanism is used, increasing the yield of SOA production (experiments 6 and 7) reduces the correlation coefficient at Hyytiälä to 0.37 (Org2), 0.16 at Aspvreten (Org2), and 0.14 at Pallas (Org2). The inclusion of biogenic SOA improves the correlation between simulated and observed values for each set of simulations at all three locations, primarily by increasing summertime N$_{80}$ concentrations.

We also compared simulated surface-level CCN concentrations to a subset of the CCN data set compiled by Spracklen et al. (2011a). The treatment of primary carbonaceous emissions has been shown to strongly influence particle number concentrations and aerosol size distributions simulated by global aerosol microphysics models (Reddington et al., 2011; Spracklen et al., 2011a). We therefore compared against measurements filtered to minimise the influence of these particles: that is, data for terrestrial locations with a typical background for Aspvreten, Pallas, Finland; very remote location against European pollution location but influenced by boreal forest location, mid-Sweden; observed and simulated CCN concentrations calculated from [CCN]$_{expt}$. 4/[CCN]$_{expt. 20}$ less than 2, during times when the site was reported to be unaffected by wildfire emissions. This subset of data contained 25 observations (each representing a time-weighted mean CCN concentration from a sampling period of days to weeks) from the six locations detailed in Table 4. Relative uncertainties in the observational data set all lie in the range ±5–40 %, but most within ±10–20 %. CCN concentrations from the model were calculated for each of the six locations using the supersaturation at which the observations were recorded.

Table 3 reports the normalised mean bias (NMB) between multi-annual monthly mean observed and simulated monthly mean N$_{80}$ concentrations. The normalised mean bias (NMB, %) in surface CCN concentration between model and observations is also given for each simulation. The simulation with the best correlation at each location, or smallest NMB, is highlighted in bold.

We also compared simulated surface-level CCN concentrations to a subset of the CCN data set compiled by Spracklen et al. (2011a). The treatment of primary carbonaceous emissions has been shown to strongly influence particle number concentrations and aerosol size distributions simulated by global aerosol microphysics models (Reddington et al., 2011; Spracklen et al., 2011a). We therefore compared against measurements filtered to minimise the influence of these particles: that is, data for terrestrial locations with a typical background for Aspvreten, Pallas, Finland; very remote location against European pollution location but influenced by boreal forest location, mid-Sweden; observed and simulated CCN concentrations calculated from [CCN]$_{expt}$. 4/[CCN]$_{expt. 20}$ less than 2, during times when the site was reported to be unaffected by wildfire emissions. This subset of data contained 25 observations (each representing a time-weighted mean CCN concentration from a sampling period of days to weeks) from the six locations detailed in Table 4. Relative uncertainties in the observational data set all lie in the range ±5–40 %, but most within ±10–20 %. CCN concentrations from the model were calculated for each of the six locations using the supersaturation at which the observations were recorded.

Table 3 reports the normalised mean bias (NMB) between observed and simulated CCN concentrations calculated according to Eq. (6) where $S_i$ are CCN number concentrations simulated by the model, and $O_i$ are observed CCN number concentrations at each location, $i$.

$$\text{NMB} = 100\% \times \sum (S_i - O_i) / \sum O_i$$  (6)
Fig. 4. Multi-annual monthly mean observed (black lines) seasonal cycle in $N_{80}$ concentration at Hyytiälä (left) and Pallas (right); standard deviation of the observed monthly mean is indicated by the vertical black lines. $N_{80}$ concentrations simulated using the ACT (green; expt. 1 and expt. 4) and Org1 (red; expt. 15 and expt. 16) nucleation mechanisms are shown with biogenic SOA (full lines) and without (dotted lines).

Fig. 5. Annual mean absolute (left) and percentage (right) change to CDNC due to biogenic SOA when the ACT nucleation mechanism is used (i.e. $[\text{CDNC}]_{\text{expt. 4}} - [\text{CDNC}]_{\text{expt. 1}}$).

In the absence of biogenic SOA, CCN concentrations are under-predicted by the model (NMB = $-44.4\%$ for ACT, $-48.6\%$ for Org1 and $-26.6\%$ for Org2). Inclusion of biogenic SOA reduces the NMB at these locations, and to within the uncertainty associated with the observational data set, e.g. from $-44.4\%$ to $-16.0\%$ with ACT. Whilst the inclusion of monoterpane emissions in the particle formation rate (experiments 16 and 18) improved the correlation with the observed seasonal cycle at the European sites, simulations Org1 and Org2 lead to an over-prediction (NMB = $+16.9\%$ for Org1 and $+20.0\%$ for Org2) of CCN concentration, which is still, however, within the uncertainty of the measurements.

When biogenic SOA is included, but is not able to age non-hydrophilic particles to the hydrophilic distribution, CCN concentrations are under-predicted (NMB = $-40.5\%$) suggesting that despite selecting for relatively pristine locations and times, the ageing of carbonaceous particles still contributes to local CCN concentrations. The faster rate of ageing makes little difference to the correlation (NMB = $-16.5\%$, as compared to $-16.0\%$ for the standard ageing), suggesting that the process of generating CCN-active particles through physical ageing is not limited by the availability of condensable material in these locations. This is confirmed by the narrow range of NMB values obtained for experiments 4 to 7 ($-16.0\%$ to $-17.2\%$), over which the yield of SOA production is varied by a factor of 10. When the smaller emission size for BC/POM particles is used (experiment 12), CCN concentrations are substantially over-predicted (NMB = $+48.2\%$), suggesting that this emission size generates too many CCN-active particles in the presence of SOA.

Fig. 6. Annual mean absolute (left) and percentage (right) change to CDNC due to biogenic SOA (monoterpenes only) when the Org1 nucleation mechanism is used (i.e. $\Delta[CDNC]_{\text{expt.16}} - [CDNC]_{\text{expt.15}}$).

5 Cloud droplet number concentrations

We simulate that biogenic SOA increases the global annual mean CDNC by between 1.9 % and 5.2 % when the ACT nucleation mechanism is used (Table 2). Figure 5 shows the spatial distribution of the annual mean change in CDNC due to the presence of biogenic SOA, when the ACT mechanism is used and emissions of both monoterpenes and isoprene are included. Over most regions, perturbations to calculated CDNC follow the same spatial pattern as changes to CCN concentration. However, in regions with high pre-existing aerosol concentrations, such as those heavily affected by biomass burning, activation of additional CCN to cloud droplets can become limited by competition for water vapour. This is evident over South America and western Africa, where the largest changes to CDNC (Fig. 5) do not coincide spatially with the largest changes to CCN (Fig. 1). As with CCN, relatively low absolute changes to CDNC in the SH can lead to high fractional changes over the oceans. In the boreal regions, the inclusion of biogenic SOA increases the annual mean CDNC by up to 70 % due to very low background CDNC and therefore a high sensitivity to additional CCN. Small decreases (< 10 %) in CDNC occur over the tropical oceans due to the decreases in CCN described in Sect. 3.1. As with CCN, including monoterpane oxidation products in the particle formation rate equation yields the greatest increase in CDNC due to biogenic SOA (26.6 % and 7.2 % for Org1 and Org2 respectively). Figure 6 shows the spatial distribution of the annual mean CDNC change when the Org1 mechanism is used; as with CCN, large absolute increases are simulated at around 40° N, whilst fractional increases in excess of 100 % are simulated above 60° N (Fig. 3).

6 Radiative effect of biogenic SOA

We calculate a global mean DRE of between $-0.08$ W m$^{-2}$ and $-0.78$ W m$^{-2}$ for biogenic SOA in the present-day atmosphere (Table 2), with the spatial distribution of the effect for experiment 4 shown in Fig. 7 (left). Figure 8 (left) shows the sensitivity of the global annual mean DRE to the processes examined in this study. The magnitude of the DRE is highly sensitive to the amount of SOA (and therefore the amount of growth of particles) included in the simulation, with the global annual mean varying from $-0.09$ W m$^{-2}$ when the SOA production yield is halved (source of 18.5 Tg(SOA) a$^{-1}$), to $-0.78$ W m$^{-2}$ when the yield is increased by a factor of 5 (source of 185.1 Tg(SOA) a$^{-1}$). As such, the DRE is strongest over the tropics where BVOC emissions are highest (Fig. 7, left).
Changes in the nucleation mechanism result in little variability in the DRE (range $-0.08$ W m$^{-2}$ to $-0.10$ W m$^{-2}$). The large increase in the number of nucleated particles and CCN simulated with the organic nucleation mechanisms is less important for the direct effect as these particles are too small to influence the path of incoming solar radiation. The DREs simulated by Rap et al. (2013) and O’Donnell et al. (2011) lie within the range we calculate here. Goto et al. (2008) calculated a smaller DRE of $-0.01$ W m$^{-2}$, but included less SOA ($\sim 7$ Tg(SOA) a$^{-1}$), and used a mass-only aerosol model which does not simulate the growth of particles associated with the condensation of secondary organic material.

We calculate that in the present-day atmosphere, biogenic SOA exerts a global annual mean first AIE of between $+0.01$ and $-0.77$ W m$^{-2}$ (Table 2). Figure 7 (right) shows the spatial distribution in the first AIE due to biogenic SOA in a simulation using the ACT mechanism (experiment 4). A negative first AIE occurs in locations experiencing a large relative increase in CDNC (e.g. boreal Asia), or a modest increase in CDNC coinciding with a high fraction of low level cloud cover (e.g. SH oceans). A positive first AIE occurs in locations where a small decrease in CDNC (Fig. 5) coincides with very high cloud fraction, such as the western coasts of central America and Africa (Fig. 7, right).

Figure 8 (right) summarises the sensitivity of the global annual mean first AIE to the processes examined in this study. The simulated global annual mean first AIE is most sensitive to the nucleation mechanism used in the model (global annual mean range $-0.05$ W m$^{-2}$ to $-0.77$ W m$^{-2}$); the inclusion of monoterpene oxidation products in the particle formation rate results in greater CCN and CDNC increases, and therefore a more negative first AIE, than either the BHN or ACT mechanisms. As with the ACT simulation, both organic nucleation mechanisms generate a negative first AIE over the oceans between 30° S and 50° S, but Org1 in particular also yields large negative forcings in the NH due to high fractional CCN and CDNC changes between 40° N and 60° N (Fig. 3).

Using the smaller size characteristics for primary carbonaceous emissions gives greater CCN and CDNC increases due to biogenic SOA, and subsequently a more substantial first AIE of $-0.12$ W m$^{-2}$. When secondary organic material is not able to age non-hydrophilic particles to the hydrophilic distribution, the global annual mean first AIE is reduced to $-0.02$ W m$^{-2}$, due to smaller increases in CCN and CDNC. Whilst increasing the yield of SOA production gives a greater global annual mean fractional increase in CDNC (Table 2), the increased yield enhances negative CDNC changes in regions with very high cloud fraction, so the first AIE becomes less negative (e.g. $-0.04$ W m$^{-2}$ when the SOA yield is doubled).

Over boreal forests, regional annual mean first AIEs of between $-0.1$ W m$^{-2}$ and $-0.5$ W m$^{-2}$ are calculated with the ACT mechanism (Fig. 7, right) and between $-0.1$ W m$^{-2}$ and $-1.5$ W m$^{-2}$ with the Org1 nucleation mechanism.

As illustrated in Fig. 9, much of the boreal region experiences a summertime (JJA) mean first AIE of between $-1$ W m$^{-2}$ and $-5$ W m$^{-2}$, when the Org1 mechanism is used, matching the large cooling effect over these forest regions calculated by previous studies (Kurten et al., 2003; Spracklen et al., 2008a; Lihavainen et al., 2009). However, the strongest regional radiative effect (up to $-9$ W m$^{-2}$) is simulated over the North Atlantic ocean (50–60°N) which, whilst experiencing a smaller CDNC increase than the land regions at the same latitude, has higher cloud coverage in the ISCCP data set (i.e. cloud fraction of 50–70% as compared to 0–30% over the land). In agreement with Lihavainen et al. (2009) we find that over the boreal region, the simulated first AIE is substantially greater than the DRE (Fig. 7).

The AIE from monoterpene SOA ($-0.19$ W m$^{-2}$) estimated by Goto et al. (2008) lies within the range of first AIE we calculate here. The first AIE of $-0.02$ W m$^{-2}$ calculated
Fig. 8. Variation in global annual mean DRE (left) and first AIE (right) of biogenic SOA associated with several parameters; black bars indicate the range of values obtained for each set of experiments: Nucl (nucleation mechanism; expt. 2, 14, 16, 18), Yield (SOA yield; expt. 4, 5, 6, 7), Pri Carb (primary carbonaceous emission size; expt. 4, 12), Age (physical ageing; expt. 4, 8, 10).

Fig. 9. Summertime (JJA) mean first AIE from monoterpene SOA when the Org1 nucleation mechanism is used (expt. 16).

by Rap et al. (2013) was for a GLOMAP simulation using BHN (as in our experiment 14) and required only one soluble monolayer to transfer non-hydrophilic particles to the hydrophilic distribution (as in our experiment 10), and is in line with the first AIEs calculated here. O’Donnell et al. (2011) simulated a positive AIE (+0.23 W m$^{-2}$) for all SOA (i.e. biogenic plus anthropogenic), which lies outside our range (between +0.01 and −0.77 W m$^{-2}$). The positive AIE simulated by O’Donnell et al. (2011), may be caused by the secondary organic material being distributed preferentially amongst larger size particles (i.e. those already large enough to act as CCN), resulting in a decrease in global mean CDNC. We examine the sensitivity of the biogenic SOA AIE to assumptions concerning the part of the aerosol size distribution to which SOA is added (i.e. volatility treatment of the condensable material), in a further publication (Scott et al., 2014).

There is a large difference between the spatial pattern of the DRE and first AIE due to biogenic SOA. This is mainly driven by the distribution of clouds since a high cloud fraction will suppress any potential DRE from changes to particle number and size below, but will enhance any potential AIE from changes to particle number and size. Consequently, the DRE tends to be stronger over the relatively less cloudy (based on the ISCCP clouds for the year 2000) land regions and the first AIE tends to be stronger over the relatively more cloudy ocean regions. For example, in the ACT simulation shown in Fig. 7, the DRE is more than a factor of 5 greater than the first AIE over central Africa and South America, whereas the first AIE is more than a factor of 5 greater than the DRE over high-latitude Northern and Southern Hemisphere ocean regions.

7 Sensitivity of the radiative effect of biogenic SOA to anthropogenic emissions

Primary particulate (POM and BC) and gas-phase (SO$_2$) emissions from anthropogenic sources were much lower in 1750 than in the present day. These lower emissions result in lower simulated background (i.e. in the absence of biogenic SOA) concentrations of CCN. The radiative effect of biogenic SOA may therefore have been different in a pre-industrial atmosphere. To explore this possibility we simulated the impact of biogenic SOA in an atmosphere with 1750 anthropogenic emissions (experiments 19 and 20; ACT_1750). Including biogenic SOA in a pre-industrial atmosphere yields a lower absolute change in CCN number concentration than in the present day. This lower absolute change is due to fewer ultrafine particles being available (from nucleation and primary sources) for growth to CCN sizes, or ageing, by the secondary organic material. Despite the lower absolute change, the inclusion of biogenic SOA results in a higher fractional change of +23.2 % (Table 2), due to lower background CCN concentrations in the pre-industrial atmosphere. This increased fractional change in CCN, combined with lower background CDNC, results in a greater perturbation to CDNC due to biogenic SOA in a
pre-industrial atmosphere (global annual mean +12.6 %, as compared to +4.4 % in the present day).

Since the fractional change in CDNC constrains the first AIE (Eq. 5), a more substantial indirect effect of $-0.19 \text{ W m}^{-2}$ is simulated with 1750 anthropogenic emissions (experiment 20; ACT_1750) compared to $-0.06 \text{ W m}^{-2}$ with the same model setup in the present day. Regions of both positive and negative change in CDNC are enhanced by the lower background concentration, so this global mean radiative effect represents a combination of NH land and SH ocean regions experiencing a more negative first AIE and tropical oceans experiencing a more substantial positive first AIE (Fig. 10), as compared to an equivalent simulation using present-day anthropogenic emissions (Fig. 7, right).

The global mean first AIE obtained using the Org1 particle formation mechanism (experiment 22; Org1_1750) is also enhanced in the 1750 atmosphere ($-0.95 \text{ W m}^{-2}$ as compared to $-0.77 \text{ W m}^{-2}$ in the present day). The annual mean first AIE is more negative at most latitudes, but at 30–50° S, the radiative effect is stronger in the present-day simulation (solid red line in Fig. 10, right) due to higher SO$_2$ emissions in southern Africa and Australia, required to generate the H$_2$SO$_4$ needed to form new particles using the Org1 nucleation mechanism.

Increasing the SOA yield when 1750 anthropogenic emissions are used results in a greater fractional enhancement to CCN than when present-day anthropogenic emissions are used (Fig. 11, left). This enhanced CCN sensitivity translates into a greater CDNC and first AIE sensitivity and has implications for the first aerosol indirect radiative forcing (RF) due to anthropogenic aerosol emissions. To test this, we calculate an anthropogenic first indirect RF since 1750, by setting CDNC$_1$ in Eq. (5) to the present day, and CDNC$_2$ to the value obtained from a simulation using anthropogenic emissions from 1750. We find that the first aerosol indirect RF from anthropogenic emission changes (1750 to present) is $-1.16 \text{ W m}^{-2}$ when we assume a low source of biogenic SOA (18.5 Tg(SOA) a$^{-1}$) but decreases in absolute value to $-1.10 \text{ W m}^{-2}$ when we assume a large source (185.1 Tg(SOA) a$^{-1}$) (purple circles in Fig. 11, right).

If the Org1 mechanism is used in both present-day and 1750 simulations (red circle in Fig. 11, right), the calculated aerosol indirect RF is $-1.04 \text{ W m}^{-2}$, that is 0.12 W m$^{-2}$ smaller than that derived using the ACT mechanism and an equivalent SOA source strength. The variation in first indirect anthropogenic RF, due to uncertainties in SOA yield and nucleation mechanism, highlights the need to understand the baseline pre-industrial atmosphere and the magnitude of pre-existing natural radiative effects in order to constrain the RFs due to human activities. A previous study demonstrated that uncertainty in volcanic SO$_2$ emissions plays a similar role in driving uncertainty in the anthropogenic first aerosol indirect RF (Schmidt et al., 2012).

By contrast, the DRE of biogenic SOA is less sensitive to the presence of anthropogenic emissions. When the ACT mechanism is used, the same DRE is simulated with present-day and 1750 anthropogenic emissions ($-0.18 \text{ W m}^{-2}$). When the Org1 mechanism is used, DREs of $-0.08 \text{ W m}^{-2}$ and $-0.12 \text{ W m}^{-2}$ are simulated with present-day and 1750 anthropogenic emissions respectively. The DRE is slightly enhanced in the 1750 atmosphere because there is less organically mediated new particle formation than in the present day ($\Delta N_3 = +643.0 \text{ cm}^{-3}$ in the present day, and $+437.3 \text{ cm}^{-3}$ in the 1750 atmosphere), due to lower SO$_2$ emissions. As a result, there are fewer nucleation mode particles requiring condensable material for growth in the 1750 atmosphere, and a greater proportion of the secondary organic...
8 Summary and conclusions

We used a global aerosol microphysics model (GLOMAP) and an offline radiative transfer model to quantify the impact of biogenic SOA on CCN concentrations and CDNC, and the subsequent radiative implications.

In all present-day simulations, the global annual mean CCN concentration increases (by between 3.6 % and 45.2 %) when biogenic SOA is included. In the absence of organically mediated nucleation, most of the simulated increase in CCN number concentration occurs due to physical ageing, and subsequent growth, of non-hydrophilic particles originating from wildfire and carbonaceous combustion. However, when monoterpane oxidation products affect the new particle formation rate, CCN concentrations are mostly perturbed by the growth of newly formed particles to CCN-active sizes. Similarly, at around 60° N, where monoterpane emissions are high during the NH summer months and background particle concentrations are low, a greater proportion of the CCN increase is associated with the growth of smaller particles. Regional decreases in CCN concentrations are simulated, in particular over the tropical oceans, due to enhanced nucleation scavenging of non-hydrophilic particles, and the suppression of upper tropospheric and boundary layer nucleation. The spatial changes to CDNC from the inclusion of biogenic SOA broadly match changes to CCN concentrations, with global annual mean increases ranging from 1.9 % to 26.6 %. However, the magnitude of CDNC change becomes limited by competition for water vapour in highly polluted regions, such as those affected by biomass burning. The low sensitivity of CCN to the inclusion of biogenic SOA in experiments without organically mediated nucleation is consistent with the much larger parameter sensitivity study of Lee et al. (2013). In this sensitivity study, biogenic SOA production was varied between 5 and 360 Tg(SOA) a⁻¹, which resulted in a global mean 3 % standard deviation in CCN concentration, with a maximum standard deviation of approximately 40 % locally. Our results confirm the suggestion of Lee et al. (2013) that organically mediated nucleation would greatly increase the sensitivity of CCN to SOA.

The radiative effect attributed to biogenic SOA is uncertain. We calculate that biogenic SOA results in a present day global annual mean all-sky top-of-atmosphere DRE of between −0.08 W m⁻² and −0.78 W m⁻², and a first AIE of between +0.01 W m⁻² and −0.77 W m⁻². This range extends our previous estimates of −0.13 W m⁻² for the DRE and −0.02 W m⁻² for the first AIE of biogenic SOA (Rap et al., 2013). The DRE is most sensitive to the yield of SOA production and strongest in regions of high BVOC emission. Increasing or decreasing the yield of SOA production from the base case values reduces the agreement with observations of particle number greater than 80 nm diameter (N₈₀) at three forested locations (Table 3). Our best estimate of the DRE from biogenic SOA is therefore −0.18 W m⁻², consistent with a global production of 37 Tg(SOA) a⁻¹. The largest uncertainty in the first AIE of biogenic SOA comes from the representation of new particle formation in the boundary layer, specifically whether organic compounds contribute to the very early stages of new particle formation. Including the oxidation products of monoterpenes in the particle formation rate equation gives a first AIE from biogenic SOA up to 11 times greater than when sulphuric acid alone controls new particle formation. The best agreement between...

simulated and measured seasonal cycles in N$_{80}$ is obtained when monoterpane oxidation products affect the new particle formation rate, suggesting that the magnitude of the global annual mean first AIE from biogenic SOA could lie towards the upper end of our estimated range of $-0.77$ W m$^{-2}$. The observations of N$_{80}$ used here are restricted to boreal forest locations in northern Europe; long-term observations of N$_{80}$ in other forest ecosystems will be required to give tighter constraints on the global radiative effect of biogenic SOA.

Figure 12 compares the radiative effect of biogenic SOA calculated here against the radiative effects of other natural aerosol sources and the anthropogenic aerosol radiative forcing. The radiative effects of natural aerosol sources are similar in magnitude to the anthropogenic aerosol RF, as has been previously documented (Rap et al., 2013). Our upper estimates of the radiative effects of biogenic SOA exceed the radiative effects of the other natural aerosol sources (DMS, volcanic sulphate, sea salt and wildfires) examined by Rap et al. (2013). Narrowing the large uncertainty in the radiative effect of biogenic SOA is therefore a prerequisite for a better understanding of the relative roles of natural aerosol in the climate system.

At high northern latitudes, monoterpane emissions from boreal forests result in a summertime regional first AIE of up to $-6$ W m$^{-2}$ over land, and $-9$ W m$^{-2}$ over ocean, when organic compounds influence the new particle formation rate (Org1 mechanism). Previous studies (Betts, 2000; Snyder et al., 2004; Bala et al., 2007; Davin and de Noblet-Ducoudré, 2010) suggest that the low land-surface albedo of boreal forests exerts a warming (i.e. positive radiative effect) on the climate which potentially outweighs the cooling effect (i.e. negative radiative effect) due to carbon storage by these forests. Follow-up work is required to examine the radiative effect of biogenic SOA in comparison to these other effects in order to quantify the overall climate impact of boreal forests.

When the present-day anthropogenic aerosol emissions in our simulations are replaced with those from 1750, the lower background aerosol concentrations result in a greater proportion of additional CCN becoming activated and therefore a more substantial first AIE from biogenic SOA in the pre-industrial atmosphere ($-0.19$ W m$^{-2}$ and $-0.95$ W m$^{-2}$ for ACT and Org1 respectively). As such, the first AIE from biogenic SOA in 1750 is more sensitive to changes in the amount of SOA generated and the nucleation mechanism used, adding uncertainties of 0.06 W m$^{-2}$ and 0.12 W m$^{-2}$ respectively to the magnitude of the first aerosol indirect RF from anthropogenic emissions since 1750 (Fig. 11, right). SOA formation from BVOCs may be enhanced by anthropogenic pollution (Heald et al., 2011; Hoyle et al., 2011; Spracklen et al., 2011b); consequently, global SOA formation may have been quite different in a pre-industrial atmosphere. We did not explore this coupling here, but the wide range of SOA production that we analysed is likely to cover both pre-industrial and present-day levels of SOA production.

As emissions of both biogenic and anthropogenic aerosol change in the future, our understanding of their effects and interactions will gain increasing importance. Emissions of BVOCs will be sensitive to future changes in climate (e.g. Lathière et al., 2005; Tunved et al., 2008; Paasonen et al., 2013), vegetation (Heald et al., 2008), and carbon dioxide concentrations (Heald et al., 2009; Pacífico et al., 2012). Additionally, changes in the spatial distribution of BVOC emissions are likely to be as important as the global magnitude of emissions, as has been shown for changes to oceanic DMS emissions (Woodhouse et al., 2013).

We have shown here that the role of organic oxidation products in new particle formation is particularly important in determining the indirect radiative effect of biogenic SOA. However, our understanding of which secondary organic species contribute to each stage of new particle formation and growth at different particle sizes is far from complete (e.g. Kulmala et al., 2013). In the absence of a detailed understanding, and bearing in mind computational costs, future model development regarding biogenic SOA could proceed on the basis that at least some (as yet undetermined) fraction of the secondary organic oxidation products contribute to new particle formation. Our simulations also highlight the important interaction between secondary organics and primary particles from combustion, particularly from fires in the tropics. This suggests that the (simulated) ageing of insoluble particles should be determined by the availability of condensable material, rather than prescribed (i.e. transferring insoluble particles to the soluble distribution after a fixed period of time), in order to capture the sensitivity of CCN concentration to changing levels of secondary organics.

Our results indicate that biogenic SOA very likely exerts a negative radiative effect in the present-day climate, via both the direct and first indirect effect, and that the magnitude of these effects is highly sensitive to our understanding of SOA.
yield and aerosol microphysical processes. Our work also reinforces the need to fully understand the influences of natural components on the Earth system in order to accurately determine the radiative effects of human activities.
