Abstract. Aromatic hydrocarbons are associated with direct adverse human health effects and can have negative impacts on ecosystems due to their toxicity, as well as indirect negative effects through the formation of tropospheric ozone and secondary organic aerosol, which affect human health, crop production and regional climate. Measurements of aromatic hydrocarbons were conducted at the Welgegund measurement station (South Africa), which is considered to be a regionally representative background site. However, the site is occasionally impacted by plumes from major anthropogenic source regions in the interior of South Africa, which include the western Bushveld Igneous Complex (e.g. platinum, base metal and ferrochrome smelters), the eastern Bushveld Igneous Complex (platinum and ferrochrome smelters), the Johannesburg–Pretoria metropolitan conurbation (> 10 million people), the Vaal Triangle (e.g. petrochemical and pyrometallurgical industries), the Mpumalanga Highveld (e.g. coal-fired power plants and petrochemical industry) and also a region of anticyclonic recirculation of air mass over the interior of South Africa. The aromatic hydrocarbon measurements were conducted with an automated sampler on Tenax-TA and Carbopack-B adsorbent tubes with heated inlet for 1 year. Samples were collected twice a week for 2 h during daytime and 2 h during night-time. A thermal desorption unit, connected to a gas chromatograph and a mass spectrometric detector was used for sample preparation and analysis. Results indicated that the monthly median (mean) total aromatic hydrocarbon concentrations ranged between 0.01 (0.011) and 3.1 (3.2) ppb. Benzene levels did not exceed the local air quality standard limit, i.e. annual mean of 1.6 ppb. Toluene was the most abundant compound, with an annual median (mean) concentration of 0.63 (0.89) ppb. No statistically significant differences in the concentrations measured during daytime and night-time were found, and no distinct seasonal patterns were observed. Air mass back trajectory analysis indicated that the lack of seasonal cycles could be attributed to patterns determining the origin of the air masses sampled. Aromatic hydrocarbon concentrations were in general significantly higher in air masses that passed over anthropogenically impacted regions. Inter-compound correlations and ratios gave some indications of the possible sources of the different aromatic hydrocarbons in the source regions defined in the paper. The highest contribution of aromatic hydrocarbon concentrations to ozone formation potential was also observed in plumes passing over anthropogenically impacted regions.

1 Introduction

Atmospheric measurements – which include, but are not limited to, speciated volatile organic compounds and other trace gases, as well as size-resolved aerosols – are well established in developed countries. However, less emphasis is placed on such environmental issues in developing countries, since resources are mostly utilised for economic growth. For
this reason, Africa is one of the least studied regions with respect to air quality (Laakso et al., 2006). South Africa has the largest industrialised economy in Africa and is known for its diverse anthropogenic pollutant sources, which include agriculture, metallurgical and mining operations, coal-fired power generation, petrochemical operations, coal dumps and transportation (Lourens et al., 2011). Unique meteorological conditions are prevalent in South Africa, which include relatively high atmospheric temperatures and solar radiation, which increases photochemical activity in the atmosphere, and dominant anticyclonic climatology and the presence of low-level inversion layers in winter cause trapping of pollutants (Tyson et al., 1996).

Atmospheric volatile organic compounds (VOCs) are emitted from both natural and anthropogenic sources (Bates et al., 2000; Brasseur et al., 1999; Hewitt, 1999). Anthropogenic VOC emissions result from petrochemical industries, combustion processes (e.g. fossil fuel, power plants), vehicular emissions, storage and transport of fuel, usage and production of solvents, hazardous waste facilities and landfills (Srivastava et al., 2005; Derwent et al., 2000; Kourtidis et al., 1999; Jose et al., 1998). Biomass burning (veld fires) can also be an important source of VOCs, especially in southern Africa, where large-scale biomass combustion occurs every year in the dry season (e.g. Crutzen and Andreae, 1990; Crutzen et al., 1979). However, these emissions are difficult to evaluate, as they are highly dependent on fuel type, humidity and burn rate (Lobert et al., 1990).

A large fraction of anthropogenic VOCs consists of aromatic hydrocarbons, of which benzene; toluene; ethylbenzene; and o-, m- and p-xylene (BTEX) are the most commonly measured compounds. Aromatic hydrocarbons participate in complex chemical reactions in the atmosphere to form secondary pollutants. Although reactions of aromatic hydrocarbons do not directly produce ozone (O$_3$), they play a role in O$_3$ formation when they are oxidised by the hydroxyl radical (·OH) in the troposphere, producing peroxy radicals (RO$_2^-$) and hydroperoxy radicals (HO$_2^-$), which then oxidise nitric oxide (NO), which removes a sink for O$_3$ (Atkinson, 2000). Aromatic hydrocarbons can also react with nitrate radicals (NO$_3^-$) (Atkinson, 1994; Penkett et al., 1993) and halogen radicals (Finlayson-Pitts et al., 1986). Various researchers have investigated gas-phase photooxidation of aromatic hydrocarbons (e.g. Birdsell et al., 2010; Arey et al., 2009; Coeur-Tourneur et al., 2006; Johnson et al., 2004, 2005; Takekawa et al., 2003; Calvert et al., 2002, and references therein; Olariu et al., 2002; Volkamer et al., 2002).

VOCs are also associated with adverse human health effects (Mukund et al., 1996; Kostiainen, 1995; Sweet and Vermette, 1992; Edgerton et al., 1989; Duce et al., 1983) and can also be harmful to ecosystems (Atkinson, 2000; Dewulf and Van Langenhove, 1997; Kuran and Sojak, 1996; Derwent, 1995). Benzene, for instance, is known as a genotoxic carcinogen (Hellén et al., 2002; WHO, 2000) and is closely linked to the induction of leukaemia. Studies have also indicated that VOCs can have detrimental impacts on crop production, which is important for global food security (Zunckel et al., 2006).

Limited research has been conducted to determine the emission rates of biogenic VOCs in southern Africa (Harley et al., 2003; Otter et al., 2002a, 2002b; Swap et al., 2002a, 2002b; Greenberg et al., 2002; Greenberg et al., 1999; Guenther et al., 1996). Even fewer data are available to characterise aromatic VOC levels in South Africa. Benzene is the only aromatic hydrocarbon that has a standard included in the National Ambient Air Quality Standards (NAAQS) (Government Gazette, 2009). According to the knowledge of the authors, only Lourens et al. (2011) has conducted a study in this region on BTEX concentrations that was published in the peer-reviewed public domain. This study was limited to measurements in the industrialised Mpumalanga Highveld and Vaal Triangle for 1 year. Additionally, some postgraduate studies focusing on BTEX have been conducted (van der Walt, 2008; Burger, 2006; Chiloane, 2005), but these were not published in the peer-reviewed public domain. Various industries also perform VOC measurements in South Africa to comply with legislation, but these results are in most instances not peer-reviewed and not available in the public domain.

To at least partially address the above-mentioned knowledge gap, i.e. very limited data on atmospheric aromatic hydrocarbons in South Africa, measurements were conducted for 1 year at the Welgegund measurement station. This station was strategically positioned to enable measurements of air masses that have passed over the regional background, as well as all the major anthropogenic source regions in South Africa (Beukes et al., 2014).

2 Measurement location and methods

2.1 Site description

The Welgegund measurement station (www.welgegund.org) is situated approximately 100 km west of Johannesburg (Fig. 1) on the property of a commercial farmer. The station is considered to be a regionally representative background site with no direct impacts from pollution sources in close proximity. The entire western sector (from north to south-east) contains no major point sources and can therefore be considered as representative of a relatively clean regional background. The site is, however, impacted by plumes from major anthropogenic source regions in the interior of South Africa, which include the western Bushveld Igneous Complex (WBIC), the eastern Bushveld Igneous Complex (EBIC), the Johannesburg–Pretoria metropolitan conurbation (> 10 million people), the Vaal Triangle, the Mpumalanga Highveld and also a region of anticyclonic recirculation of air mass over the interior of South Africa. The impacts of regional biomass combustion occurring mainly in
the dry winter and spring are also observed at Welgegund. A detailed description of the Welgegund measurement station and related source regions was recently presented by Beukes et al. (2014). In Fig. 1, the location of Welgegund is indicated (latitude 26°34′10″ S, longitude 26°56′21″ E; 1480 m a.s.l.) within a regional perspective, which also indicates the large point sources and source regions.

2.2 Measurement methods

The measurement instruments were placed inside a Eurowagon 4500u (length 4.5 m, width 2.1 m, height 2.3 m) measurement container. A detailed description of the measurement instruments, operation procedures and data analysis, as well as calibration and maintenance procedures has been presented by Beukes et al. (2014), Tiitta et al., 2014, Petäjä et al. (2013), Hirsikko et al. (2012), Venter et al. (2012), Vakkari et al. (2011) and Laakso et al. (2008).

2.2.1 Aromatic hydrocarbon measurements

The VOC measurement campaign was conducted for 1 year (9 February 2011 to 4 February 2012) to observe seasonal variability. Samples were collected twice a week for 2 h during daytime (11:00 to 13:00 local time, LT) and 2 h during night-time (23:00 to 1:00LT) on Tuesdays and Saturdays. Obviously this repetitive sampling schedule, i.e. same days each week and same hours of the day, was prone to some bias. Large point sources, i.e. industrial stack emissions, in South Africa are regulated on an availability basis. This implies that off-gas cleaning equipment must be operational for a certain percentage of the overall operating time (typically 97–99 %) and not on a time basis, e.g. specific days or hours when emissions are allowed. It was therefore impossible to set a sampling schedule to capture possible large releases of VOCs by such point sources. Traffic emissions, which can be considered as a point or area source, depending on how far the emissions are from the measurement site, are another example of a potential time-bound VOC source that had to be considered. At the Welgegund site only a small gravel road, used by a few farmers, is nearby. Local traffic emissions are therefore almost negligible. Large traffic volumes in especially the Johannesburg–Pretoria megacity could be a significant area source of VOCs for Welgegund. However, since Welgegund is ∼100 km west of Johannesburg, it was difficult to set a sampling schedule to capture such time-bound emissions that are transported at different rates on different days with different meteorological conditions. Considering the remote nature of the sampling site and logistical limitations during the sampling campaign, the sampling schedule applied was the most feasible option that enabled the collection of a full year of data. VOCs were sampled at a height of 2 m above ground level, with a 1.75 m long inlet. The first 1.25 m of the inlet was made of stainless steel and the second 0.5 m of Teflon. The first 1.2 m of the stainless steel section of the inlet was heated to 120°C using heating cables and thermostats (Thermionic) to remove O₃, which could possibly lead to sample degradation (Hellén et al., 2012). The last 0.05 m of the stainless steel section and the entire Teflon section was housed within the measurement container, wherein the temperature was regulated at 24°C. The O₃ removal efficiency was checked with an O₃ monitor at regular intervals, which revealed that O₃ concentrations decreased from median values ≥ 30 ppb (Beukes et al., 2014) to < 2 ppb.

Prior to sampling, all adsorbent tubes were tested for leaks and preconditioned with helium for 30 min at 350°C at a flow of 40 mL min⁻¹. After treatment, the tubes were sealed with Swagelok® brass 0.25 in. caps and stored in a fridge at temperatures below 18°C before they were transported to the field for sampling. VOC samples were collected on Tenax-TA and Carbopack-B adsorbent tubes (6.3 mm ED × 90 mm, 5.5 mm ID) by using a constant-flow-type automated programmable sampler. A needle valve attached to the pump was used to keep the flow constant, while magnetic valves were used to direct flow to a specific sample tube. After a specific tube was sampled, the tube was automatically sealed off and the next tube selected for sampling. The flow of the pump was calibrated each week. A sampling flow between 100 and 110 mL min⁻¹ was used throughout the study. Hellén et al. (2002) reported no breakthrough for Tenax-TA and Carbopack-B tubes when sampling for 4 h at a flow rate of 100 mL min⁻¹. Once a week, the tubes were removed from the automated sampler and closed with Swagelok® caps. Each tube was separately wrapped in aluminium foil and stored in a container for transport to the laboratory. Tubes were stored in the laboratory in a freezer within a clean environment to minimise pre-analysis elution and breakdown of the sampled compounds. For each month, a field blank was analysed to compensate for the possibility of contamination from sample handling and storage. The total concentration of aromatic hydrocarbons in all field blanks was found to be < 0.076 ppb. Actual concentrations of all compounds reported in this paper were significantly higher than blank
values and also well above the detection limits. Blank values were subtracted from exposed samples.

The analyses and preparation of the adsorbent tubes were done by the Finnish Meteorological Institute. The instrumental setup was a thermal desorption instrument (Perkin-Elmer TurboMatrix™ 650, Waltham, USA) connected to a gas chromatograph (Perkin-Elmer® Clarus® 600, Waltham, USA) with a DB-5MS (60 m, 0.25 mm, 1 µm) column and a mass selective detector (Perkin-Elmer® Clarus® 600T, Waltham, USA). The sample tubes were desorbed at 300°C for 5 min and cryofocused in a Tenax cold trap (−30°C) prior to injection of the sample into the column by rapidly heating the cold trap (40°C min⁻¹) to 300°C. A three-point calibration curve was obtained by using liquid standards dissolved in methanol. Standard solutions were injected into adsorbent tubes and were flushed with nitrogen (100 mL min⁻¹) for 10 min in order to evaporate the methanol. The tubes containing the standards were desorbed and analysed with the same method used for the sampled tubes. Thirteen aromatic hydrocarbons were detected and quantified during this study.

2.2.2 Ancillary measurements

Trace gas measurements continuously conducted at Welgegund were used to assist in the interpretation of aromatic hydrocarbon results obtained. These were measured by utilising a Thermo-Electron 43S sulfur dioxide (SO₂) analyser (Thermo Fisher Scientific Inc., Yokohama-shi, Japan), a Teledyne 200AU NOₓ analyser (Advanced Pollution Instrumentation Inc., San Diego, CA, USA), an Environment SA 41M O₃ analyser (Environment SA, Poissy, France) and a Horiba APMA-360 CO analyser (Horiba, Kyoto, Japan). A more detailed description of additional parameters monitored at Welgegund is given by Beukes et al. (2014) and Petäjä et al. (2013).

2.2.3 Air mass back trajectory analysis

Individual hourly back trajectories were calculated with the Hybrid Single-Particle Lagrangian Intergrated Trajectory (HYSPLIT) model version 4.8, developed by the National Oceanic and Atmospheric Administration (NOAA) Air Resources Laboratory (ARL) (Draxler and Hess, 2004). This model was run with meteorological data of the GDAS archive of the US National Weather Service’s National Center for Environmental Prediction (NCEP) and archived by the ARL (Air Resources Laboratory, 2012). Each hourly arriving back trajectory was calculated for 96 h (4 days) backwards. An arrival height of 100 m was chosen, since aromatic hydrocarbons are mainly emitted within the lowermost layer of the troposphere. Furthermore, the orography in HYSPLIT is not very well defined, and therefore lower arrival heights could result in larger error margins on individual trajectory calculations. Back trajectories were calculated for the start, middle and end of each measurement period, i.e. 3-hourly arriving back trajectories calculated for each 2 h sample.

3 Results and discussion

3.1 Contextualising aromatic hydrocarbon concentrations measured at Welgegund

The monthly mean (median) aromatic hydrocarbon concentrations determined in this study ranged between 0.011 (0.01) and 3.2 (3.1) ppb. As previously mentioned, benzene is currently the only VOC listed as a criteria pollutant in the NAAQS (Lourens et al., 2011; Government Gazette, 2009), with an annual average limit of 1.6 ppb (2015 standard). The Welgegund annual mean (median) benzene concentration was 0.29 (0.13) ppb, which is well below the South African standard. The highest benzene concentration measured was 8.7 ppb, which indicates that the site is occasionally significantly impacted by pollution sources. Liu et al. (2000), who conducted a study in a relatively non-polluted area in the northeast of China, reported an average benzene concentration of 9.4 µg m⁻³ (2.94 ppb). Lourens et al. (2011) reported an annual median of 0.91 ppb in the Mpumalanga Highveld and the Vaal Triangle, which is higher than the annual median value measured at Welgegund. This can be attributed to the measurement sites in the Mpumalanga Highveld and the Vaal Triangle being closer to the large point sources than Welgegund. In another investigation, van der Walt (2008) measured benzene levels in a South African metropolitan area and reported an annual mean of 1.8 ppb. A comparison of the benzene concentrations measured at Welgegund with these studies indicates that Welgegund can be considered as a regional background site that is on occasion impacted by major plumes from different sources.

Toluene was the most abundant aromatic hydrocarbon, with an annual mean (median) concentration of 0.89 (0.63) ppb – nearly 5 times higher than the benzene annual median concentration. Lourens et al. (2011) also reported ambient toluene concentrations to be substantially higher than that of benzene over the interior of South Africa. Considering that toluene also has negative effects on human health, as well as that it is a precursor for O₃ and secondary organic aerosol formation, it should be considered to be included in future South African air quality legislation.

The second and third most abundant aromatic hydrocarbons measured were styrene and (m,p)-xylene with annual mean (median) concentrations of 0.83 (0.66) and 0.77 (0.50) ppb, respectively. α-Xylene and ethyl benzene had annual mean (median) concentrations of 0.30 (0.20) and 0.34 (0.25) ppb, respectively. The other aromatic hydrocarbons measured had annual median concentrations that were significantly lower. This does not necessarily mean that their emission sources were lower, since the ambient concentrations are...
Figure 2. Monthly annual variation in aromatic hydrocarbon concentrations measured during the 1-year sampling period. The red line of each box indicates the median (50th percentile), the black dot the mean, the top and bottom edges of the box the 25th and 75th percentiles, and the whiskers ± 2.7σ or 99.3 % coverage if the data have a normal distribution (MATLAB, 2010). The values displayed near the top of the graphs indicate the number of samples (N) analysed for each month.
determined by the emission rate and their atmospheric lifetimes (Parra et al., 2006).

3.2 Temporal variations

Although samples were collected during daytime and nighttime in order to identify possible diurnal influences, results indicated no statistically significant differences in the concentrations of aromatic hydrocarbons measured during daytime and nighttime. Also, no statistically significant differences were observed between Tuesdays and Saturdays. This indicates that there are no major local sources such as traffic that would result in a distinct diurnal pattern. Therefore, no distinction in the results was made in subsequent sections based on daytime and nighttime, or day of the week.

The monthly temporal variations of the measured aromatic hydrocarbons are presented in Fig. 2. These figures indicate the median, mean and 25th and 75th percentiles, as well as ±2.7 of the quartiles for each compound (Matlab, 2010). The number of samples collected per month (N) is also provided. In general, no distinct seasonal pattern is observed for any of the compounds measured. The results indicate relatively high values during February 2011 and March 2011 for all the aromatic hydrocarbons, with the exception of benzene. If these higher values coincided with a seasonal cycle, it would have been expected that similar higher values had been observed in the corresponding months in the next year, which was not the case. The reason for these higher levels of aromatic hydrocarbons observed during these 2 months will be explored in Sect. 3.3. No seasonal patterns for BTEX were observed in a previous investigation conducted in the Mpumalanga Highveld and Vaal Triangle (Lourens et al., 2011).

3.3 Influence of source regions

Since no distinct seasonal cycles could be identified for the measured aromatic hydrocarbons (Fig. 2), the possible influence of air masses passing over different source regions on the concentration of these compounds was explored. Since VOCs were collected for only four 2 h sampling periods per week, the allocation of hourly back trajectories to air masses passing over all of the source regions defined by Beukes et al. (2014) was statistically not significant. Therefore, it was decided to group the Johannesburg–Pretoria megacity, the Vaal Triangle and the Mpumalanga Highveld source regions together, since these source regions were identified by Beukes et al. (2014) as the regions with the highest anthropogenic impacts. In this paper, this combined source regions will be referred to as area I. The WBIC, the EBIC and the anticyclonic source regions that lie on the anticyclonic recirculation path of air masses moving towards Welgegund (Beukes et al., 2014) were grouped together and are referred to as area II. Lastly, the “regional background” source region was kept as defined by Beukes et al. (2014). In Fig. 3, the different source regions considered in this study are presented.

For the entire VOC measurement period, 582 back trajectories were generated. Back trajectory sets, i.e. three trajectories per sampling period, were classified as passing over the different source regions defined in Fig. 3. For the two anthropogenically influenced source regions, i.e. areas I and II, only back trajectory sets that had passed over one of these source regions were considered. Therefore, back trajectory sets that had passed over both these source regions were not considered in further discussions on the influence of source regions. Back trajectory sets were considered as passing over the regional background if such trajectories did not pass over either area I or II, or both area I and II. Taking this into consideration, 86 % of all back trajectory sets could be classified as passing over just one of the three source regions defined.

In Fig. 4, the back trajectories of air masses passing over the different source region are presented. In total, 39 % of the VOC samples were collected during periods when air mass back trajectory sets had passed over area II, while 33 and 14 % of VOC samples were collected when air mass back trajectory sets passed over the regional background and area I, respectively. The reason for the lower percentage of air masses passing over area I can be attributed to the persistence of the anticyclonic circulation pattern over the interior of South Africa, which favours the arrival of air masses at Welgegund from the north to north-eastern sector.

In Fig. 5, the monthly fractional distribution of VOC samples collected during periods when air mass back trajectory
sets had passed over the different source regions is presented. In this figure, air masses that had passed over multiple source regions were defined as mixed. The monthly fractional distribution (Fig. 5) can possibly be used to explain the lack of seasonal pattern observed for the aromatic hydrocarbons (Fig. 2). During February 2011, more than 60% of the air masses that arrived at Welgegund passed over area I, which consists of the Johannesburg–Pretoria metropolitan conurbation, the Vaal Triangle and the Mpumalanga Highveld. According to Lourens et al. (2012), the Johannesburg–Pretoria megacity is relatively heavily polluted, while both the Vaal Triangle and the Mpumalanga Highveld source regions have been included in areas declared as pollution hotspots (national priority areas) by the South African government (Government Gazette, 2007; Government Gazette, 2005). Considering the high frequency of air masses arriving at Welgegund after passing over area I during the initial period of the study (Fig. 5), the relatively high aromatic hydrocarbon levels measured in February 2011 and March 2011 (Fig. 2) can be related to the relatively polluted air masses arriving during this period. Conversely, during the rest of the study, most of the air masses that arrived at Welgegund passed only over area II and the regional background, which corresponds to lower concentrations measured (Fig. 2). It is therefore postulated that the monthly seasonal cycles presented for the aromatic hydrocarbons (Fig. 2) are not directly related to seasonal patterns in emissions, but rather depend on the origin of the air masses sampled. Any monthly differences are likely to be a result of month-to-month differences in air mass trajectories. The aforementioned postulation is strengthened by a slight concentration increase in most of the aromatic hydrocarbons observed during August and September 2011 (Fig. 2), which correlated with an increase in frequency of the arrival of air masses that had passed over area I (Fig. 5).

The aromatic hydrocarbon concentrations measured for air masses passing over the three source regions are presented in Fig. 6. As expected, aromatic hydrocarbon concentrations were in general significantly higher for air masses that passed over area I, which are considered to be more polluted. Air masses that passed over area II and the regional background had much lower aromatic hydrocarbon levels and were of the same order. The large point sources in area II are mainly pyrometallurgical smelters (Fig. 2) that produce metals from ores by means of reducing processes (e.g. ferrochromium, as indicated by Beukes et al., 2010, 2012). Aromatic hydrocarbon emissions are not usually associated with these activities and so the relatively low values are expected. In addition, the large point sources in area II are on average further away from Welgegund than the large point sources in area I. This longer travelling time can result in the increased oxidation of the aromatic hydrocarbons. Aromatic hydrocarbons measured in air masses from the regional background can possibly be attributed to smaller cities and agricultural activities in this region, but may also be associated with natural emissions (e.g. Heiden et al., 1999).

### 3.4 Inter-compound correlations: an indication of sources

Several authors (Hoque et al., 2008, and references therein) have performed correlation analyses to determine the possible source(s) for aromatic hydrocarbons. In this section, Pearson’s correlation analyses were applied to correlate the concentrations of the different aromatic hydrocarbons...
Figure 6. BTEX concentrations measured in air masses arriving at Welgegund, after they had passed over the defined source regions. The red line of each box indicates the median (50th percentile), the black dot the mean, the top and bottom edges of the box the 25th and 75th percentiles, and the whiskers ±2.7σ or 99.3% coverage if the data have a normal distribution (MATLAB, 2010). The values displayed near the top of the graphs indicate the number of samples (N) analysed for each source area.
measured to one another, as well as to trace gas concentrations for air masses passing over each of the three source regions defined. These correlations are graphically presented in Fig. 7.

For air masses that had passed over area I, relatively good correlations ($r > 0.8$) between the aromatic hydrocarbons were observed, except for benzene. The correlations of benzene with the other aromatic hydrocarbons were less significant, i.e. $r > 0.6$. This indicates that all the aromatic hydrocarbons, except possibly benzene, could be from similar sources. Karl et al. (2009) used aircraft flux measurements to show that toluene to benzene ratios can vary greatly (factor of 3 to factor of 15) on a spatial scale of tens of kilometres, indicating differences associated with various sources within a region, indicating that a high correlation between benzene and toluene will not always be the case. Large coal-fired power stations and petrochemical operations in source area I, together with vehicle emissions, are expected to be the dominant sources of aromatic hydrocarbons in this source region. Venter et al. (2012) recently indicated that household combustion, which is a very common occurrence in semi- and informal settlements in particular, could also contribute significantly. None of the aromatic hydrocarbons correlated with any of the inorganic gaseous compounds, except benzene, which had a correlation coefficient of 0.612 with CO. Benzene also showed a negative correlation with O$_3$. Both the correlation with CO and the negative correlation with O$_3$ indicate that benzene was mainly present in fresher plumes arriving at Welgegund. The partial correlation of benzene with CO indicates that incomplete combustion sources such as vehicle emissions, household combustion and biomass combustion may be the dominant benzene emissions sources in area I.

With the exception of benzene and toluene, the other aromatic hydrocarbons in air masses that had passed over area II correlated relatively well ($r > 0.73$) with one another. Although benzene and toluene did not correlate with the other aromatic hydrocarbons, they correlated relatively well ($r = 0.74$) with one another. Therefore, it seems that benzene and toluene had a similar source(s), while the other aromatic hydrocarbons had a different source(s). However, neither benzene nor toluene correlated with CO, as was the case for benzene in air masses that had passed over area I. Incomplete combustion sources were therefore unlikely to be the main sources of these two compounds. The nature of large point sources in area II is dramatically different to that of area I. Virtually no large combustion point sources occur in area II, since pyrometallurgical operations mainly focusing on reductive smelting are dominant.

For air masses that had passed over the regional background, benzene correlated well ($r = 0.92$) with toluene. However, in contrast to air masses that had passed over areas I and II, not all of the remaining aromatic hydrocarbons correlated with one another. Only a few significant correlations existed, e.g. ethylbenzene, styrene, $(m,p)$-xylene and $o$-xylene correlated well ($r > 0.8$) with each other. This indicates that the sources of benzene and toluene were again linked but that the sources of the other aromatic hydrocarbons were not necessarily linked. The lower concentrations measured in air masses that had passed over the regional background will not be as well correlated.

Figure 7. Correlation analysis for aromatic hydrocarbons with one another and with inorganic trace gases in samples that were collected when back trajectory sets had passed over area I (a), area II (b) and the regional background (c).

The aromatic hydrocarbon ratios also resulted in more uncertainty, which could lead to lower correlations. Additionally, the natural emissions of aromatic hydrocarbons were also explored. Heiden et al. (1999) proved that some plant species release toluene. Of the species evaluated by Heiden et al. (1999), only sunflower is relevant to the situation at Welgegund—sunflower is the second most common crop species in the area. Heiden et al. (1999) stated that significant diurnal variation in toluene emissions from sunflowers occur, with daytime emissions being a factor of 2 higher than night-time emissions. This was attributed to either differences in photo active radiation (PAR) and/or temperature (T) between daytime and night-time. As is evident from Fig. 7c, toluene did not correlate or anti-correlate with T for the regional background. Therefore, although it is not impossible that vegetation contributes to toluene concentrations measured, it does not seem to be the dominant source.

3.5 Inter-compound ratios: an indication of sources and aging

In addition to inter-compound correlations, inter-compound ratios can also be used as an indicative method to determine possible sources for aromatic hydrocarbon and the age of air masses (Hoque et al., 2008, and references therein). The inter-compound ratios of the average atmospheric concentrations of aromatic hydrocarbons with benzene are presented in Table 1. Since most of the aromatic hydrocarbons are more reactive than benzene, the toluene / benzene (T/B), (m,p)-xylene / benzene ((m,p)-X/B), o-xylene / benzene (o-X/B) and (m,p)-xylene / ethylbenzene ((m,p)-X/EB) ratios can provide information on the distance from emission sources and the estimated photochemical age of the air mass (Monod et al., 2001; Derwent et al., 2000). The atmospheric T/B ratio, for instance, is usually high close to anthropogenic emissions and will decrease with an increase in distance from the sources (Lee et al., 2002). Globally a T/B ratio below 3 was found to be characteristic of fresh emissions originating from traffic, while a T/B ratio > 4.3 is typical for solvent sources (Lan et al., 2013, and references therein).

As indicated in Table 1, the highest aromatic hydrocarbon ratios were observed for plumes passing over area I, whereas lower ratios were detected in plumes passing over area II and the regional background. The ratios (calculated from the average concentrations) for plumes passing over area I were 6.51, 7.31, 2.84, 2.55 and 2.87 for (T/B), ((m,p)-X/B), (o-X/B) ((m,p)-X/EB) and (EB/B), respectively. These ratios indicate the influence of anthropogenic activities in this area, as well as the closer proximity of especially the Johannesburg–Pretoria megacity, which is part of area I, to the Welgegund monitoring station.

The ratios for plumes passing over area II were 2.38, 1.97, 0.76, 2.20 and 0.89 for (T/B), ((m,p)-X/B), (o-X/B) ((m,p)-X/EB) and (EB/B), respectively. As mentioned previously, although anthropogenic activities are also present in this source area, the major industrial activities in this area are not usually associated with high emissions of VOCs. Additionally, sources in area II are also further away from the measurement site compared to sources in area I. The ratios therefore also indicate aged air masses, which might be transported by the dominant anticyclonic circulation pattern of air masses from the industrial hub of South Africa. Therefore, it is likely that most of the aromatic hydrocarbons in air masses that had passed over area II had undergone photochemical degradation.

For air masses passing over the regional background, the aromatic hydrocarbon inter-compound ratios were 2.66, 2.05, 0.85, 2.19 and 0.93 for (T/B), ((m,p)-X/B), (o-X/B) ((m,p)-X/EB) and (EB/B), respectively. These ratios compared well with the ratios calculated for area II, which also indicate no local sources of atmospheric aromatic hydrocarbons.

According to the literature, the use of solvents (e.g. in paint) is thought to be a major non-traffic source of aromatic hydrocarbons. Brocco et al. (1997) stated that toluene, ethylbenzene and o,m,p-xylene (TEX) make up the largest portions of solvents. In Fig. 8, the concentration ratios of TEX/total aromatics for air masses that had passed over the three sources regions are illustrated. The ratios show a

Note: TMB stands for trimethylbenzene.

seasonal pattern with the maximum values in summer and minimum in winter. This is similar to the observation made by Rappenglück and Fabian (1999) who reported that the evaporation of solvents makes a greater contribution to atmospheric VOCs during summer. The average temperatures measured during the sampling periods, as presented in Fig. 8, also indicate a similar pattern than the TEX concentration ratios. This further supports the hypothesis that TEX concentrations are strongly influence by the effect of temperature on evaporation rates. Although not tested in this paper, it is, however, also possible that the differences in aromatic hydrocarbon lifetimes between the different season could result in the aforementioned temporal pattern. It is therefore clear that aromatic hydrocarbons originating from solvents make a contribution to aromatic hydrocarbons in air masses that had passed over all three source regions, including the regional background. However, the magnitude of this contribution was not determined from these data.

3.6 O₃ formation potential of aromatic hydrocarbons

While the evaluation of aromatic hydrocarbons on a concentration (ppb) basis is of interest in order to assess human exposure to toxic compounds such as benzene, it is also of interest to examine the relative importance of these pollutants pertaining to their role in the production of O₃ (Carter, 1994). Beukes et al. (2014), Laakso et al. (2013) and Venter et al. (2012) indicated that O₃ is currently the most problematic pollutant in South Africa. Tropospheric O₃ impacts air quality, food security (Zunckel et al., 2006) and regional climate change (Fry et al., 2013). Therefore, the relative contributions of aromatic hydrocarbons to photochemical O₃ formation in air masses that had passed over the three source regions were examined. Several reactivity scales can be used to estimate O₃ formation for specific hydrocarbons. One method that determines the ability of aromatic hydrocarbons to produce O₃ entails calculating the product of the average concentration and the maximum incremental reactivity coefficient (MIR) of each compound, i.e. O₃ formation potential = VOC × MIR (Carter, 1994). The MIR scale has been used to assess O₃ formation potential for aromatic hydrocarbon in numerous previous studies (Hoque et al., 2008; Na et al., 2005; Grosjean et al., 1998).

The ranking of the aromatic hydrocarbons according to air mass origin for O₃ formation potential is provided in Table 2. As indicated (Table 2), the highest contributions of aromatic hydrocarbon concentrations to O₃ formation potential were observed for plumes passing over area I. The O₃ formation potential for air masses that had passed over area II and the regional background was of the same order of magnitude. Based on the O₃ formation potential values, xylenes ((m,p)-xylene plus o-xylene) are the dominant contributor to O₃ formation for air masses that have passed over area I, with 1,2,4-trimethylbenzene the second largest contributor. The O₃ formation potential of benzene was the lowest, even though it is considered to be the most hazardous compound of the atmospheric aromatic hydrocarbons. As previously stated, the use
of solvents (e.g. in paint) is thought to be a major non-traffic source of aromatic hydrocarbons, with toluene, ethylbenzene and \( o,m,p \)-xylene (TEX) making up the largest portion of solvents (Brocco et al., 1997). It was also shown that the ratio of TEX/total aromatic hydrocarbons followed a typical seasonal pattern, demonstrating the contribution from solvents (Fig. 8) in all three source regions. From Table 2 it is evident that TEX contributes significantly to \( O_3 \) formation relative to the other compounds considered in this paper. The contribution of the evaporation of solvents to \( O_3 \) formation as a fraction of the overall aromatic hydrocarbons \( O_3 \) formation potential therefore seems to be significant.

4 Conclusions

Benzene is the only VOC listed as a criteria pollutant in the NAAQS, and had an annual average (median) of 0.29 (0.13) ppb, which was well below the South African standard limit of 1.6 ppb. Toluene was the most abundant aromatic hydrocarbon, with an annual average (median) concentration of 0.89 (0.63) ppb. Lourens et al. (2011) also previously reported ambient toluene concentrations in the interior of South Africa as being significantly higher than that of benzene. It is therefore recommended that a national air quality threshold for toluene be considered in future. Since the concentrations of ethylbenzene, \( (m,p) \)-xylene, \( o \)-xylene and styrene were also of the same order as that of toluene, these compounds could also be considered for inclusion in such legislation.

No statistically significant differences in the concentrations of aromatic hydrocarbons measured during daytime and night-time, or during Tuesdays and Saturdays, were found. This indicates the lack of local sources. However, it should be regarded as an important future perspective to set sampling schedules that would eliminate all possible time-bound biases. This could be achieved with continuous online analysis, which would also enable proper assessment of diurnal cycles and specific case studies. Additionally, no distinct seasonal patterns were observed for any of the compounds measured, which could be attributed to the origin of the air masses sampled. Aromatic hydrocarbon concentrations were in general significantly higher in air masses that had passed over anthropogenically influenced source regions.

Inter-compound correlations indicated that all the aromatic hydrocarbons, except benzene, originated from the same source(s) in area I, where benzene most likely originated from incomplete combustion. For area II and the regional background, benzene and toluene were found to originate from the same source(s), while all the other aromatic hydrocarbons were emitted by a different source(s). Inter-compound ratios indicated the influence of anthropogenic activities, especially in area I, and also the closer proximity of the Johannesburg–Pretoria megacity in area I to the Welgegund monitoring station, i.e. less aged plumes. The concentration ratios of TEX/total aromatics for air masses that had passed over the three sources regions indicated a seasonal dependence, i.e. higher temperatures resulting in higher evaporation rates that contribute to higher ambient concentrations. The highest contributions of aromatic hydrocarbon concentrations to \( O_3 \) formation potential were observed for plumes passing over area I. Xylenes (\( (m,p) \)-xylene plus \( o \)-xylene) were the dominant contributor to \( O_3 \) formation, with 1,2,4-trimethylbenzene being the second largest contributor. The \( O_3 \) formation potential of benzene was the lowest.
