Abstract. Atmospheric aerosols exert highly uncertain impacts on radiative forcing and also have detrimental effects on human health. While aerosol particles are widely characterized in megacities in China, aerosol composition, sources and particle growth in rural areas in the Tibetan Plateau remain less understood. Here we present the results from an autumn study that was conducted from 5 September to 15 October 2013 at a national background monitoring station (3295 m a.s.l.) in the Tibetan Plateau. The submicron aerosol composition and particle number size distributions were measured in situ with an Aerodyne Aerosol Chemical Speciation Monitor (ACSM) and a Scanning Mobility Particle Sizer (SMPS). The average mass concentration of submicron aerosol (PM1) is 11.4 µg m−3 (range: 1.0–78.4 µg m−3) for the entire study, which is much lower than observed at urban and rural sites in eastern China. Organics dominated PM1, accounting for 43 % on average, followed by sulfate (38 %) and ammonium (11 %). Positive Matrix Factorization analysis of ACSM organic aerosol (OA) mass spectra identified an oxygenated OA (OOA) and a biomass burning OA (BBOA). The OOA dominated OA composition, accounting for 85 % on average, 17 % of which was inferred from aged BBOA. The BBOA contributed a considerable fraction of OA (15 %) due to the burning of cow dung and straw in September. New particle formation and growth events were frequently observed (80 % of time) throughout the study. The average particle growth rate is 2.0 nm h−1 (range: 0.8–3.2 nm h−1). By linking the evolution of particle number size distribution to aerosol composition, we found an elevated contribution of organics during particle growth periods and also a positive relationship between the growth rate and the fraction of OOA in OA, which potentially indicates an important role of organics in particle growth in the Tibetan Plateau.

1 Introduction

High concentration of atmosphere aerosol associated with the rapid economic growth, urbanization and industrialization has become a major environmental concern in China. Aerosol particles, especially fine particles (PM2.5), have large impacts on human health, the natural ecosystem, weather and climate, radiative balance and the self-purification capacity of the troposphere (Jacobson, 2001; Tie and Cao, 2009). As a result, a large number of studies have been conducted to investigate the sources, chemical and physical properties and evolution processes of aerosol particles at urban and rural sites in China during the last decade (Cao et al., 2007; Wu et al., 2007; He et al., 2011; Gong et al., 2012; Huang et al., 2013; Sun et al., 2013, 2015; Jiang et al., 2015). The results showed that fine particles are mainly composed of organics, sulfate, nitrate, ammonium, mineral dust and black carbon. The sources of organic aerosol (OA)
were also characterized and various OA factors from distinct sources were identified, including primary OA (POA), e.g., hydrocarbon-like OA (HOA), cooking OA (COA), biomass burning OA (BBOA) and coal combustion OA (CCOA); and secondary OA (SOA), e.g., semi-volatile oxygenated OA (SV-OOA) and low-volatility OOA (LV-OOA) (Huang et al., 2010, 2011; Sun et al., 2010, 2014; He et al., 2011; Xu et al., 2014a). While previous studies significantly improve our understanding on the sources and chemical properties of aerosol particles, they were mainly conducted in developed areas in China, including Beijing–Tianjin–Hebei, Pearl River Delta and Yangtze River Delta.

The Tibetan Plateau (∼2000 000 km$^2$) is the highest plateau in the world, with an average altitude of over 4000 m a.s.l. The Tibetan Plateau is an ideal location for characterizing rural and regional background aerosol due to minor influences of anthropogenic activities. However, chemical characterization of aerosol particles in the Tibetan Plateau is rather limited, and therefore their sources, properties and evolution processes are poorly known. Cong et al. (2015) reported the seasonal variations of various aerosol components, including carbonaceous species and water-soluble ionic species on the south edge of the Tibetan Plateau. Sulfate was found to dominate the total ionic mass (25 %), followed by nitrate. In addition, most aerosol species showed pronounced season variations in the pre-monsoon period due to biomass burning impacts from India and Nepal. Zhao et al. (2013) also characterized the chemical composition and sources of total suspended particulate (TSP) at Lulang on the southeastern TP, based on 1 year of measurements. Similar seasonal variations with higher concentrations during the pre-monsoon period were observed. The back trajectory analysis showed evident transport of air pollutants from south Asia to the TP. The analysis of size-segregated aerosol samples collected at a remote site in the inland of the Tibetan Plateau during 2012 further confirmed the high concentrations of organic carbon (OC) and elemental carbon (EC) during the pre-monsoon period (Wan et al., 2015), although their concentrations in PM$_{1}$ (2.38 and 0.08 µg m$^{-3}$, respectively) were much lower than those reported in eastern China. Most studies above were conducted in the southeastern Tibetan Plateau. Comparatively, aerosol particles showed quite different behavior in the northeastern Tibetan Plateau. Li et al. (2013) investigated the sources and chemical composition of five particles collected at a remote site (Qinghai Lake) in the summer of 2010 in the Tibetan Plateau. The average PM$_{2.5}$ concentration was 22 ± 13 µg m$^{-3}$ with sulfate and carbonaceous aerosol being the two major species. Xu et al. (2014b) conducted a year-long measurement of PM$_{2.5}$ composition at the Qilian Shan station. The annual average concentration of PM$_{2.5}$ was 9.5 ± 5.4 µg m$^{-3}$, with water-soluble ions accounting for 39 % of total mass. Water-soluble ions were dominated by sulfate (39 %) and showed pronounced seasonal variations. The aerosol composition, size distributions and back trajectory analysis together indicated a mixed impact of both mineral dust from arid areas of northwest China and anthropogenic emissions from urban areas. However, previous extensive efforts to characterize the chemical properties of aerosol particles in the Tibetan Plateau heavily rely on filter measurements; with the duration ranging from days to weeks, real-time measurement of aerosol particle composition is still very limited. A recent study by Xu et al. (2014a) deployed a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) at an urban site in Lanzhou in northwest China. The submicron aerosol in the city was dominated by organic aerosol (47 %) with a large contribution from local traffic and cooking emissions (40 %). To our knowledge, there is no such real-time measurement of aerosol particle composition with aerosol mass spectrometer at rural sites in the Tibetan Plateau yet.

The study of new particle formation and growth events in the Tibetan Plateau is also relatively new. Since 2004, a number of studies have been conducted to investigate the new particle formation (NPF) and particle growth events in various environments in China (Wu et al., 2007; Wiedensohler et al., 2009; Yue et al., 2010; Y. M. Zhang et al., 2011; Wang et al., 2013a, b). The NPF events were frequently observed in urban cities, rural sites, coastal regions and mountain sites. Sulfuric acid was found to play a dominant role in both NPF and subsequent particle growth, while organics make an important contribution to particle growth (Yue et al., 2010). The particle growth rates varied largely, depending on sites and days, yet generally fell within 1–20 nm h$^{-1}$. Kivekäs et al. (2009) conducted a long-term measurement of particle number size distributions at Waliguan, a global baseline site located approximately 140 km southwest of our sampling site. The annual average particle number concentration was found to be higher than other rural sites in the world. Despite this, the particle growth and its relationship to chemical species in the Tibetan Plateau are rarely investigated and remain poorly understood.

In this study, an Aerodyne Aerosol Chemical Speciation Monitor (ACSM) was first deployed at a national background monitoring site (Menyuan, Qinghai) in the Tibetan Plateau for the real-time characterization of submicron aerosol composition including organics, sulfate, nitrate, ammonium and chloride from 5 September to 15 October, 2013. Collocated measurements including black carbon and particle number size distributions were also conducted at the same site. Here we report the aerosol composition and variations of submicron aerosols and investigate the sources of organic aerosol with Positive Matrix Factorization (PMF). In addition, the particle growth events are also characterized and the roles of chemical species in particle growth are elucidated.
2 Experimental method

2.1 Sampling site

The sampling site, i.e., the national atmospheric background monitoring station (NBS) (37°36’30”N, 101°15’26”E; 3295 m a.s.l.) is located on Daban Mountain in Menyuan, Qinghai province (Fig. 1). The sampling site is characterized by a typical Plateau continental climate with a pleasantly cool and short summer and a long, cold winter. The annual average temperature is −1 to −2 °C, and the precipitation is 426–860 mm. In this study, ambient temperature averaged 4.9°C (−8.7–17.9°C) and wind speed varied, largely with an average value of 3 m s⁻¹. In addition, several precipitation events were also observed, particularly during the first half period of this study (Fig. 3). The diurnal profiles of meteorological conditions including temperature, relative humidity, wind speed and wind direction are shown in Supplement Fig. S1. The sampling site is relatively pristine with most areas covered by typical Tibetan Plateau plants, e.g., potentilla fruticosa and kobresia. There are no strong local anthropogenic source emissions in this area (~741 km² with a population of ~2000) except occasional biomass burning events due to the burning of a large amount of straw in the middle of September and cow dung at the end of the campaign (Li et al., 2015). The capital city of Qinghai province, Xining, with a population of 2,290,000, is approximately 160 km south of the sampling site, which is connected by a national road (G227) with little vehicle traffic.

2.2 Instrumentation

The field measurements were conducted from 5 September to 15 October 2013. All the instruments were placed in an air-conditioned room with the temperature maintaining at ~23 °C. The chemical compositions of non-refractory submicron aerosol (NR-PM₁) species including organics (Org.), sulfate (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺) and chloride (Cl) were measured in situ by an Aerodyne ACSM (Ng et al., 2011b). A PM₂.5 cyclone (model URG-2000-30ED) was supplied in front of the sampling line to remove coarse particles larger than 2.5 μm. The ambient air was drawn inside the room through a 1/2 inch (outer diameter) stainless steel tube using an external pump (flow rate is ~3 L min⁻¹). The sampling height is approximately 2 m, and the particle residence time in the sampling tube is ~5 s. A silica gel diffusion dryer was then used to dry aerosol particles before sampling into the ACSM. After passing through a 100 μm critical orifice, aerosol particles between 30 nm and 1 μm are focused into a narrow particle beam via the aerodynamic lens in the vacuum chamber, and then flash vaporized and ionized at a heated surface (~600 °C). The positive ions generated are finally collected at the measuring Positive Matrix Factorization (PMF2.exe, v 4.2) on ACSM OA mass spectra (Paatero and Tapper, 1994; Ulbrich et al., 2008; Middlebrook et al., 2012) because aerosol particles were dry and only slightly acidic, and also the mass fraction of ammonium nitrate during ionization efficiency (IE) calibration. A collection efficiency (CE) of 0.5 was used to account for the incomplete detection of aerosol species (Matthew et al., 2008; Middlebrook et al., 2012) because aerosol particles were dry and only slightly acidic, and also the mass fraction of ammonium nitrate is not high enough to affect CE significantly.

The sources of organic aerosol were investigated by performing Positive Matrix Factorization (PMF2.exe, v 4.2) on ACSM OA mass spectra (Paatero and Tapper, 1994; Ulbrich et al., 2008; Middlebrook et al., 2012) because aerosol particles were dry and only slightly acidic, and also the mass fraction of ammonium nitrate is not high enough to affect CE significantly.

Table 1. A summary of average mass concentrations (µg m⁻³) of PM₁ species during five episodes and the entire study. The 30 min detection limit (DLs) of the ACSM is also shown (Sun et al., 2012).

The time resolution is approximately 15 min, by alternating six cycles between the ambient air and particle-free air. The detailed operation of ACSM has been given in Sun et al. (2012).

In addition to ACSM measurements, a Scanning Mobility Particle Sizer (TSI, 3936) equipped with a long Differential Mobility Analyzer (DMA) was simultaneously operated to measure the particle number size distributions between 11.8 and 478.3 nm at a time resolution of 5 min. Other collocated measurements included CO by a non-dispersive infrared analyzer (M300EU), O₃ by a UV photometric analyzer (Teledyne Instruments, Model 400EU), NOₓ by a commercial chemiluminescence analyzer (M200EU) and SO₂ by a pulsed UV fluorescence analyzer (M100EU) and black carbon (BC) by the Aethalometer (AE31, Magee Scientific Corp). The meteorological parameters, e.g., temperature, relative humidity, pressure, visibility, precipitation, wind speed and wind direction were also recorded at the same site. All the data are reported at ambient conditions in Beijing standard time. Note that the concentrations would be a factor of approximately 1.5 of the current values if the data are converted to mass loadings at standard temperature and pressure (STP, 273 K and 1013.25 hPa).

2.3 Data analysis

The ACSM data were analyzed within Igor Pro (WaveMetrics, Inc., Oregon USA) using the standard ACSM data analysis software (v.1.5.3.0). The mass concentrations and chemical composition of NR-PM₁ species were obtained using the default relative ionization efficiency (RIE) that is 1.4, 1.2, 1.1 and 1.3 for organics, sulfate, nitrate and chloride, respectively, except ammonium (6.5) that was derived from pure ammonium nitrate during ionization efficiency (IE) calibration. A collection efficiency (CE) of 0.5 was used to account for the incomplete detection of aerosol species (Matthew et al., 2008; Middlebrook et al., 2012) because aerosol particles were dry and only slightly acidic, and also the mass fraction of ammonium nitrate is not high enough to affect CE significantly.

The sources of organic aerosol were investigated by performing Positive Matrix Factorization (PMF2.exe, v 4.2) on ACSM OA mass spectra (Paatero and Tapper, 1994; Ulbrich et al., 2008; Middlebrook et al., 2012) because aerosol particles were dry and only slightly acidic, and also the mass fraction of ammonium nitrate is not high enough to affect CE significantly.
et al., 2009). PMF is a standard multivariate factor analysis model broadly used in the field of air pollution source apportionment. The detailed PMF analysis of organic aerosol from AMS measurements, including error matrix preparation, data pretreatment, selection of the optimum number of factors and rotational forcing parameter (fpeak) and the evaluation of PMF solutions, was given in Ulbrich et al. (2009) and Q. Zhang et al. (2011). In this study, the organic mass spectra from m/z 12 to m/z 125 were used for the PMF analysis. Because of the absence of collocated measurements, the 2-factor solution with fpeak = 0 and Q/Q_{exp} close to 1 was chosen (see Fig. S2 for the PMF diagnostic plots). The two factors including a biomass burning OA (BBOA) and an oxygenated OA (OOA) were identified. The two OA factors showed largely different factor profiles and time series, indicating their distinct sources.

3 Results and discussion

3.1 Mass concentration and chemical composition of submicron aerosol

Figure 2 shows a comparison of the total PM$_{1}$ mass (NR-PM$_{1}$ + BC) with that determined from the SMPS measurements. Assuming spherical particles, the SMPS number concentrations were converted to mass concentrations using chemically resolved particle density that was estimated from the chemical composition of PM$_{1}$ (Salcedo et al., 2006). As shown in Fig. 2, the time series of PM$_{1}$ tracks well with that of SMPS measurements ($r^2$ = 0.87). The slope of 0.52 is likely due to the limited size range of SMPS measurements (12–478 nm) by missing a considerable fraction of large particles that ACSM can measure. The PM$_{1}$ mass varied dramatically throughout the study with hourly average concentration ranging from 1.0 to 78.4 µg m$^{-3}$. The average mass concentration of PM$_{1}$ for the entire study is 11.4 ($\pm$ 8.5) µg m$^{-3}$, which is $\sim$ 3–4 times lower than observed at rural sites in China (29.9–44.1 µg m$^{-3}$) (Huang et al., 2011, 2013; Hu et al., 2013; Zhang et al., 2014). It is also approximately 2 times lower than that (24.5 µg m$^{-3}$) measured at an urban site in Lanzhou in the Tibetan Plateau in 2012 (Xu et al., 2014a). While the average PM$_{1}$ mass concentration in this study is close to those observed at the remote sites in Asia, e.g., Okinawa (14.5 µg m$^{-3}$) (Zhang et al., 2007a) and Fukue (12.0 µg m$^{-3}$) (Takami et al., 2005) in Japan in 2003 and Jeju (8.6 µg m$^{-3}$) in Korea in 2001 (Topping et al., 2004), it is much higher than those reported at rural/remote sites in North America and Europe, e.g., Chebogue (2.9 µg m$^{-3}$), Storm Peak in 2004 (2.1 µg m$^{-3}$) and Hyytiala in 2005 (2.0 µg m$^{-3}$), and even comparable to the loadings at urban sites, e.g., New York City in 2004 (12 µg m$^{-3}$), Pittsburgh (15 µg m$^{-3}$) and Manchester in 2002 (14.0 µg m$^{-3}$) (Zhang et al., 2007a). These results suggest that the Menyuan NBS is a typical rural site in Asia, yet with

---

Figure 1. Map of the sampling site (Menyuan, Qinghai). Also shown is the chemical composition of submicron aerosols (NR-PM$_{1}$ + BC if it was available) measured at selected rural/remote sites in East Asia except Lanzhou, an urban site in northwest China. The two dotted blue lines are used to guide the eye for the three rural/remote regions from the west to the east. Detailed information of the sampling sites is presented in Table S1 in the Supplement.
higher background concentrations compared to those in other continents.

Figure 3 shows the time series of mass concentrations and mass fractions of aerosol species in PM$_1$. The average PM$_1$ composition is dominated by organics and sulfate, accounting for 43 and 28 % on average, respectively. Black carbon and chloride represent small fractions, contributing 4.5 and 1.2 %, respectively to PM$_1$. As shown in Fig. 1, the aerosol composition at the Menyuan NBS is largely different from that observed at the urban site in the Tibetan Plateau (Xu et al., 2014a). In particular, sulfate shows ~60 % higher contribution, yet BC is more than 2 times lower than that observed at the urban site (Fig. 1). Xu et al. (2014a) found that 47 % of BC was from local traffic emissions which explained the higher contribution of BC at the urban site well. Compared to this study, the average composition of PM$_1$ measured by the AMS at other rural sites in China showed similar dominance of sulfate (25–34 %) except Changdao Island (19 %), yet higher overall contributions of nitrate because most of these rural sites are close to urban areas with high NO$_x$ emissions. The sulfate contributions become more dominant (36–64 %) at remote sites in East Asia which are far away from urban areas. The increase of sulfate contribution is associated with a large reduction of nitrate contribution (<5 %). Such a change in aerosol bulk composition at rural/remote sites in East Asia is shown Fig. 1. Overall, organics comprises the major fraction of PM$_1$, contributing approximately one-third of the total mass at most sites. While sulfate plays a dominant role in PM$_1$ at remote sites, nitrate shows the highest contribution at the rural sites in eastern China. Such compositional differences illustrate the different sources of sulfate and nitrate. While sulfate is dominantly from regional sources and transport, nitrate is more likely influenced by anthropogenic NO$_x$ emissions over smaller regional areas.

Aerosol species also varied dramatically throughout the study. For example, organics increased rapidly from 2.9 to 77.8 µg m$^{-3}$ in 1 h on 21 September. While small variations remained for sulfate, nitrate, chloride and BC showed similarly steep increases to organics, indicating strong impacts of local biomass burning (Zhang et al., 2015). Rapid decreases of aerosol species due to the precipitation of scavenging or wind direction change were also frequently observed. For a better understanding of aerosol composition under variable meteorological conditions and sources, five episodes, two of which are from clean periods, are shown in Fig. 3d. The aerosol composition varied largely among different episodes. While the average PM$_1$ mass concentrations during the two clean episodes are similar (3.6 and 3.8 µg m$^{-3}$), the episode of Clean 2 shows a much higher contribution of organics (48 % vs. 34 %) with slightly lower sulfate (33 % vs. 36 %) than Clean 1, consistent with their different air mass trajectories (Fig. S3). The other three episodes show ~5–8 times higher mass concentration of PM$_1$ (17.6–27.2 µg m$^{-3}$) than the two clean episodes. The Ep 1 is dominated by organics (70 %), almost twice that of during the other two episodes, suggesting a largely different source. The relative contributions of sulfate and organics during Ep 2 and Ep 3 are different although the nitrate contribution is similar. These results suggest that the national background site is subject to the influences of air masses from different sources, some of which are enriched with OA, while others are dominated with aerosols mainly composed of ammonium sulfates. We also noticed that the two clean periods showed an higher overall contribution of sulfate and lower contribution of nitrate compared to the three pollution episodes. The possible reasons were likely due to the fact that the air masses during clean periods were either from a longer transport when ammonium nitrate was deposited or evaporated due to dilution processes, or from less anthropogenically influenced regions with low NO$_x$ emissions.

The aerosol particle acidity was evaluated using the ratio of measured NH$_4^+$ (NH$_4^+$ mea) to the predicted NH$_4^+$ (NH$_4^+$ pred = 18 × (2 × SO$_4^2−$/96+ NO$_3^−$/62 + Cl/35.5)) that needs to fully neutralize sulfate, nitrate and chloride (Zhang et al., 2007b). The NH$_4^+$ mea correlates tightly with NH$_4^+$ pred ($r^2 = 0.95$), yielding a regression slope of 0.80. The results suggest that aerosol particles at the Menyuan NBS are acidic overall. Similar acidic particles were also observed at other rural sites in China, e.g., Jiaxing in Yangtze River Delta (Huang et al., 2013), Kaiping in Pearl River Delta (Huang et al., 2011), Yufa in Beijing (Takegawa et al., 2009) and Qilian Shan Mountain in the northeast of the Qinghai–Xizang Plateau (Xu et al., 2015). As a comparison, the aerosol particles in the urban city Lanzhou in the Tibetan Plateau were neutralized overall (Xu et al., 2014a). One of the explanations is that more SO$_2$ is oxidized to sulfate during the transport while there is not enough gaseous ammonia to neutralize the newly formed sulfate. This is supported by the higher overall contribution of sulfate at rural/remote sites than that at urban sites. Also note that the newly formed sulfate particles during the frequent NPF events might also have played a role.

### 3.2 Diurnal variations

The diurnal cycles of aerosol species and PM$_1$ are shown in Fig. 4a. The PM$_1$ shows a pronounced diurnal cycle with the concentration ranging from 7.9 to 13.4 µg m$^{-3}$. The PM$_1$ shows a visible peak at noon and then has a gradual decrease reaching the minimum at approximately 16:00. After that, the PM$_1$ starts to build up and reaches the highest level at midnight. Such a diurnal cycle is similar to those of SO$_2$ and CO (Fig. 4d), which likely indicates that the major source of PM$_1$ at the Menyuan NBS is from regional transport. All aerosol species present similarly pronounced diurnal cycles to PM$_1$ with the lowest concentrations occurring at approximately 16:00, indicating that the diurnal cycles of aerosol species were mainly driven by the dynamics of the planetary boundary layer. Organics dominated PM$_1$ composition throughout the day, varying from 38 to 51 %. The concentra-
Figure 2. Comparison of the mass concentrations of PM$_1$ (NR-PM$_1$ + BC) measured by the ACSM and Aethalometer with that by the SMPS ($D_m=12$–478 nm): (a) time series and (b) scatter plot.

Figure 3. Time series of (a–c) meteorological variables including $T$ (temperature), RH (relative humidity), Precip. (precipitation), WS (wind speed), WD (wind direction) and Vis. (visibility), (d) mass concentrations and (e) mass fractions of PM$_1$ species. The pie charts show the average chemical composition of PM$_1$ for five episodes.

Concentration of organics at 16:00 is approximately 2 times lower than that at midnight. Sulfate shows the largest noon peak among all aerosol species, consistent with those of SO$_2$ and CO. The sulfate contributes more than 25% to PM$_1$ with the highest contribution as much as 33% between 12:00 and 14:00. Nitrate and chloride show relatively stable concentrations before 11:00 and then gradually decrease to low ambient levels during daytime. Such diurnal variations still exist after considering the dilution effects of boundary layer height using the conserved tracer CO as a reference (Fig. 4c). This indicates that gas-particle partitioning affected by temperature and humidity has played an important role in driving the diurnal variations of nitrate and chloride. Consistently, the nitrate contribution to PM$_1$ during late afternoon is $\sim 7$–8% which is much lower than that ($> 12$%) in the early morning. The diurnal variation of BC is different from that observed at the urban site in the Tibetan Plateau, where the pronounced morning peak due to traffic influences was observed (Xu et al., 2014a). In fact, BC has a good correlation with nitrate ($r^2 = 0.59$), indicating that BC likely comes dominantly from regional transport. This is also supported by the low ambient levels of NO$_3$ (2.5–5.1 µg m$^{-3}$). The contribution of BC to PM$_1$ is relatively constant, which is $\sim 4$–5% throughout the day.

3.3 OA composition and sources

PMF analysis of ACSM OA mass spectra identified two factors, i.e., a biomass burning OA (BBOA) and an oxygenated OA (OOA). The mass spectra and time series of the two OA factors are shown in Fig. 5.

3.3.1 BBOA

The mass spectrum of BBOA resembles that of standard BBOA ($r^2 = 0.82$) which is characterized by a prominent peak of $m/z$ 60 (1.1% of total signal), a tracer $m/z$ for biomass burning aerosols (Aiken et al., 2009; Cubison et al., 2011; Hennigan et al., 2011). The fraction of $m/z$ 60 in BBOA (1.1%) is also much higher than $\sim 0.3$% in the absence of biomass burning impacts (Cubison et al., 2011). BBOA correlates tightly with $m/z$ 60 ($r^2 = 0.82$) and also chloride ($r^2 = 0.52$). The ratio of BBOA to $m/z$ 60 is 55.6, which is higher than that of fresh BBOA (34.5) measured during the second Fire Lab at Missoula Experiment (FLAME II) (Lee et al., 2010). One of the explanations is that BBOA in the ambient is more aged because the $m/z$ 60 related levoglucosan can be rapidly oxidized in the atmosphere (Hennigan et al., 2010). Indeed, Zhang et al. (2015) reported a
much higher ratio of aged BBOA to m/z 60 (74.8) than fresh BBOA (16.8) during two harvest seasons in Nanjing, China. The time series of BBOA shows periodically large peaks, particularly on the days of 21 and 22 September, which were mainly from the burning of a large amount of straw in the southwest region. Relatively high concentration of BBOA was also observed at the end of the campaign due to the burning of cow dung for heating purposes because of the low temperature. The average concentration of BBOA is 0.8 (±1.5) µg m⁻³ for the entire study, accounting for 15 % of total OA on average. Although the average BBOA contribution is much lower than that measured in PRD, e.g.,
Jiaxing (~3.9 µg m\(^{-3}\), 30.1 %) (Huang et al., 2013), Kaiping (~1.36 µg m\(^{-3}\), 24.5 %) (Huang et al., 2011) and Shenzhen (~5.2 µg m\(^{-3}\), 29.5 %) (He et al., 2011), the contribution of BBOA during some strong BB plumes can reach up to 40 %, e.g., 21–22 September, indicating a large impact of biomass burning on OA at the national background site. BBOA showed a pronounced diurnal cycle which is similar to that of chloride (Fig. 5c). The BBOA concentration increased rapidly from 18:00 and reached a maximum in 2 h, likely indicating that the burning of straw and cow dung mainly occurred during this period of time. As a result, the contribution of BBOA to total OA increased from ~10 % to more than 20 %.

 subsection 3.3.2 Oxygenated organic aerosols (OOA)

Similar to previously reported OOA (Zhang et al., 2005), the mass spectrum of OOA in this study is characterized by a prominent m/z 44 peak (mainly CO\(_2^+\)). The mass spectrum of OOA also resembles that of low-volatility OOA \((r^2 = 0.88)\) (Ng et al., 2011a), yet with a higher fraction of m/z 44 \((f_{44})\). A much higher fraction of m/z 44 was reported recently in ACSM OOA spectrum than that from HR-ToF-AMS, by a comprehensive evaluation of the ACSM (Fröhlich et al., 2015). The results also showed that \(f_{44}\) has minor impacts on the mass concentrations of OOA factors, although it varies largely by a factor of 0.6–1.3. The average mass concentration of OOA is 4.1 µg m\(^{-3}\), accounting for 85 % of total OA on average. The OOA contribution is much higher than that reported at urban sites in summer (~60 %) (Huang et al., 2010; Sun et al., 2012; Xu et al., 2014a), and also higher than that (~70 %) observed at rural sites in China (Hu et al., 2013; Huang et al., 2013). These results suggest that organic aerosol was highly aged and well processed at the Menyuan NBS. In addition, aqueous-processing of OA at nighttime associated with high RH might also have played a role in forming the highly oxidized OA. The diurnal cycle of OOA was similar to that of PM\(_1\), which showed a small peak before noon, followed by a subsequent decrease until 16:00. The OOA dominated OA throughout the day varying from 80 to 90 %, indicating that OA at the Menyuan NBS was mainly composed of secondary organic aerosol.

Previous studies have shown the ubiquitously tight correlations between sulfate and highly oxidized OA because of their similar secondary nature over regional scales (Zhang et al., 2005; DeCarlo et al., 2010). While the OOA correlates well with secondary sulfate for most of the time in this study, several periods with largely different correlations were also observed (Fig. 6). As shown in Figs. 5b and 6, the weak correlation events mainly occurred during periods with strong biomass burning impacts were observed. However, it cannot be resolved by extending PMF solution to more than 2 factors because of the limitation of the PMF technique in source apportionment analysis. Similar different correlations between sulfate and LV-OOA were also observed during two research flights in Mexico City and the Central Mexican Plateau (DeCarlo et al., 2010). Following the approach suggested by DeCarlo et al. (2010), we performed a post-processing technique with external tracers on the further apportionment of OOA. We first assume that OOA and sulfate have similar sources during periods in the absence of biomass burning impacts, which is supported by their tight correlations \((r^2 = 0.74)\). An average OOA/ SO\(_4\) ratio of 1.04, i.e., \([\text{OOA}/\text{SO}_4]_{\text{NBB}}\) was obtained by performing a linear regression analysis on OOA vs. SO\(_4\). We then assume that SO\(_4\) is completely from non-biomass burning (NBB) sources during BB-impact periods. This assumption is rational because previous studies have found that fresh biomass burning emits a very small or negligible fraction of sulfate (Levin et al., 2010). The sulfate-related OOA can be calculated as OOA \times [\text{OOA}/\text{SO}_4]_{\text{NBB}}, and the excess OOA that is from different sources is then determined as

\[
\text{OOA}_{\text{post-processed}} = \text{OOA} - \text{SO}_4 \times [\text{OOA}/\text{SO}_4]_{\text{NBB}}.
\]

Because the post-processed OOA shows high concentrations during BB periods, we conclude that it is very likely to be an aged BBOA that was mixed with OOA. In fact, the mass spectrum of OOA\(_{\text{post-processed}}\) is similar to that of OOA. The fraction of m/z 60 \((f_{60})\) is 0.29 %, which is very close to ~0.3 % for non-biomass burning organic aerosol (Aiken et al., 2008). Smog chamber experiments have shown that fresh BBOA can be rapidly oxidized within 3–4.5 h (Hennigan et al., 2011). While \(f_{44}\) increases significantly, \(f_{60}\) quickly decreases to a value close to ~0.3 %. Similarly, a recent study in Nanjing resolved an aged BBOA factor with its spectrum resembling to that of OOA yet with much lower \(f_{60}\) (Zhang et al., 2015). The average concentration of aged BBOA is

Figure 6. Scatter plot of OOA vs. SO\(_4\) during BB and NBB periods. The data points are color-coded by BBOA concentrations. The pie chart shows the average composition of OA with post-processed OOA (= OOA – SO\(_4\) \times [OOA/SO\(_4\)]\(_{\text{NBB}}\)).
the sulfate-related OOA contributed 67 % on average of total OA, which is close to those observed at other rural sites in e.g., Kaiping (Huang et al., 2011) and Changdao (Hu et al., 2013).

3.4 Chemistry of particle growth

Figure 7a shows the evolution of size distributions of particle number concentrations for the entire study. New particle formation and growth events (NPE) were observed almost every day (27 in 34 days). Most NPE started at ~11:00 (sunrise is 2 h behind Beijing standard time) and persisted for more than half a day, except some NPE were interrupted by either precipitation events or strong winds. The average particle number size distributions during NPE and non-event days (non-NPE) are shown in Fig. 7b. Both NPE and non-NPE show broad size distributions with higher number concentrations occurring during NPE. Three modes with geometric mean diameter (GMD) peaking at 28, 43 and 104 nm, respectively, were resolved using a log-normal distribution fitting (Seinfeld and Pandis, 2006). The largest mode (104 nm) dominated the total number of particles, accounting for ~70 %. In contrast, the average size distribution during non-NPE was characterized by a bimodal distribution, with the GMD peaking at 59 nm and 146 nm, respectively. The peak diameters were shifted to larger sizes compared to those during NPE. Such a size shift from clean days to polluted days was also observed previously in Beijing (Yue et al., 2010). Also, the two modes showed almost equivalent contributions to the total number of particles. The average particle number concentration for the entire study is $2.4 \times 10^3 \text{ cm}^{-3}$, which is nearly an order of magnitude lower than those reported at ru-
Figure 9. (a) Time series of OOA/PM$_1$, particle growth rates and average chemical composition during particle growth periods; (b) correlation of growth rate with OOA/PM$_1$. The data points are color-coded by the PM$_1$ mass concentration.

 Particle growth rates and average chemical composition during particle growth periods.

 Figure 8 shows the diurnal evolution of particle number size distributions, aerosol composition and gaseous species during NPE and non-NPE days. The particle number size distributions during NPE were characterized by distinct bimodal distributions showing a persistent larger mode, with the GMD peaking at $\sim$ 100 nm, and a smaller mode below 50 nm. The particle growth started at approximately 11:00 from $\sim$ 20 nm, and continued to grow slowly until $\sim$ 45 nm at midnight. The maximum size particles that can grow in this study is generally smaller than those ($\sim$ 60–70 nm) observed at urban and rural sites in Beijing (Wang et al., 2013a), which is likely due to the much lower concentrations of aerosol species and precursors. All aerosol species, however, showed decreases during the particle growth period between 12:00 and 17:00, and the gaseous CO and SO$_2$ showed similar variations as aerosol species. By excluding the dilution effect of PBL using CO as a tracer, we found that organics was the only species showing a gradual increase during the particle growth period (Fig. 8a), while other species remained minor changes or even slightly decreased. The contribution of organics to PM$_1$ also showed a corresponding increase from 40 to 47 %. These results suggest that organics might have played a dominant role in particle growth at the national background site. Our conclusion is consistent with the recent findings that organics, particularly oxidized organic aerosol species, play a more important role than ammonium sulfate in particle growth (Dusek et al., 2010; Ehn et al., 2014; Setyan et al., 2014). Also note that the contribution of organics to PM$_1$ during NPE ($\sim$ 40–50 %) is higher overall than that during non-NPE ($\sim$ 30–40 %), while the sulfate contribution is correspondingly lower ($\sim$ 20–30 % vs. 30–40 %), which further supports the important role of organics during NPE. The particle growth was mixed with anthropogenic sources from 17:00, which are indicated by synchronous enhancements of both aerosol species and gaseous precursors. One of possible reasons is due to the air mass transport from downwind urban areas.

 The diurnal evolution of particle size distributions and aerosol composition during non-NPE is largely different from that during NPE. The particle number size distributions and mass concentrations of aerosol species showed a dramatic variation at noon (12:00), indicating a very different chemical and/or physical process between the first and the second half day. The aerosol particles showed an evident growth from $\sim$ 50 to 60 nm during the first 6 h, which is likely a continuation of previous NPE. Compared to the early stage of particle growth during NPE, the particle growth during non-NPE is associated with synchronous increases of both organics and sulfate. The results indicate that both organics and sulfate contribute to the particle growth after mixing with anthropogenic sources from $\sim$ 18:00 the previous day.

 We further calculated the particle growth rates (GR) for NPE events without interruptions due to meteorological changes using Eq. (2):

$$ GR = \frac{\Delta D_m}{\Delta t}. $$
where $D_m$ is the geometric mean diameter from the log-normal fitting, $\Delta D_m$ is the difference of diameter during the growth period and $\Delta t$ is the duration of growth time. The calculated GR and the corresponding average chemical composition and fraction of OOA during the growth period are shown in Fig. 9a. The GR ranges from 0.8 to 3.2 nm h$^{-1}$ with an average of 2.0 nm h$^{-1}$. The GR in this study is overall consistent with those observed at remote and/or forest sites (Eisele and McMurry, 1997; Weber et al., 1997), yet generally smaller than those measured at urban and polluted rural sites (Yue et al., 2010; Shen et al., 2011; Y. M. Zhang et al., 2011), where abundant condensable vapor and high concentrations of particulate matter facilitate the growth of particles (Wang et al., 2013a). By linking GR to aerosol composition, we found that GR at the background site is positively related to the fraction of oxidized OA, which likely indicate the important role of oxidized secondary organic aerosol in particle growth (Ehn et al., 2014). Y. M. Zhang et al. (2011) also observed a tight correlation between OOA and GR in urban Beijing, supporting the important role of OOA in particle growth. Further investigation is needed for a better understanding of the role of organic aerosol, particularly oxidized OA, in new particle formation and particle growth at the regional background site.

4 Conclusions

The aerosol particle composition and particle number size distributions were measured at a national background monitoring station in the Tibetan Plateau (3295 m a.s.l.) from 5 September to 15 October 2013. The average mass concentration of PM$_1$ is 11.4 (±8.5) µg m$^{-3}$ for the entire study, which is lower than that observed at urban and rural sites in eastern China. Organics constituted the major fraction of PM$_1$, accounting for 43 % on average, followed by sulfate (28 %) and ammonium (11 %). Several periods with the contribution of organics as high as 70 %, due to biomass burning impacts, were also observed. All aerosol species presented similar diurnal cycles that were mainly driven by the dynamics of the planetary boundary layer and regional transport. PMF source apportionment analysis resolved a secondary OOA and a primary BBOA. OOA dominated OA composition, accounting for 85 % on average, with the rest being BBOA. A post-processing technique, based on the correlation of OOA and sulfate, separated an aged BBOA which on average, accounted for 17 % of OA. New particle formation and particle growth events were frequently observed during this study. The particle growth rates varied from 0.8 to 3.2 nm h$^{-1}$ with an average growth rate of 2.0 nm h$^{-1}$. Organics were found to be the only species with gradually increased contribution to PM$_1$ during NPE. Also, a higher contribution of organics during NPE than non-NPE days was observed. These results potentially illustrate the important role of organics in particle growth. Further analysis showed a positive correlation of particle growth rate with the fraction of OOA, suggesting that oxidized OA plays a critical role in particle growth.
