Abstract. We investigate Arctic tropospheric composition using ground-based Fourier transform infrared (FTIR) solar absorption spectra, recorded at the Polar Environment Atmospheric Research Laboratory (PEARL, Eureka, Nunavut, Canada, 80°05′N, 86°42′W) and at Thule (Greenland, 76°53′N, −68°74′W) from 2008 to 2012. The target species, carbon monoxide (CO), hydrogen cyanide (HCN), ethane (C2H6), acetylene (C2H2), formic acid (HCOOH), and formaldehyde (H2CO) are emitted by biomass burning and can be transported from mid-latitudes to the Arctic.

By detecting simultaneous enhancements of three biomass burning tracers (HCN, CO, and C2H6), ten and eight fire events are identified at Eureka and Thule, respectively, within the 5-year FTIR time series. Analyses of Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) model back-trajectories coupled with Moderate Resolution Imaging Spectroradiometer (MODIS) fire hotspot data, Stochastic Inversion Lagrangian Transport (STILT) model footprints, and Ozone Monitoring Instrument (OMI) UV aerosol index maps, are used to attribute burning source regions and travel time durations of the plumes. By taking into account the effect of aging of the smoke plumes, measured FTIR enhancement ratios were corrected to obtain emission ratios and equivalent emission factors. The means of emission factors for extratropical forest estimated with the two FTIR data sets are 0.34 ± 0.21 g kg−1 for C2H6, 0.34 ± 0.21 g kg−1 for C2H2, and 2.92 ± 1.30 g kg−1 for HCOOH. The emission factor for CH3OH estimated at Eureka is 3.44 ± 1.68 g kg−1.

To improve our knowledge concerning the dynamical and chemical processes associated with Arctic pollution from fires, the two sets of FTIR measurements were compared to the Model for OZone And Related chemical Tracers, version 4 (MOZART-4). Seasonal cycles and day-to-day variabilities were compared to assess the ability of the model to reproduce emissions from fires and their transport. Good agreement in winter confirms that transport is well implemented in the model. For C2H6, however, the lower wintertime concentration estimated by the model as compared to the FTIR observations highlights an underestimation of its emission.

Results show that modeled and measured total columns are correlated (linear correlation coefficient r > 0.6 for all gases except for H2CO at Eureka and HCOOH at Thule), but suggest a general underestimation of the concentrations in the model for all seven tropospheric species in the high Arctic.

1 Introduction

Fires release trace gases into the atmosphere, affecting air quality (Colarco et al., 2004), climate, and the carbon cycle (IPCC, 2007). Those radiatively and photochem-
ically active trace gases include carbon monoxide (CO), hydrogen cyanide (HCN), and non-methane hydrocarbons (NMHCs), including ethane (C₂H₆), acetylene (C₂H₂), methanol (CH₃OH), formic acid (HCOOH), and formaldehyde (H₂CO) (Paton-Walsh et al., 2010; Akagi et al., 2011; Vigouroux et al., 2012). Given their long atmospheric lifetimes, CO, HCN, and C₂H₆ are considered to be tracers of long-range pollution transport associated with biomass burning plumes. In the Arctic, these gases and the other shorter-lived species (C₂H₂, CH₃OH, HCOOH, and H₂CO) affect the tropospheric chemistry (Generoso et al., 2007, Stohl et al., 2007, Tilmes et al., 2011), oxidizing power (Mao et al., 2010; Olson et al., 2012), and radiative transfer (Wang et al., 2011) of this sensitive polar region, which has been warming rapidly over the past century (Lesins et al., 2010). Since fire frequency and intensity are sensitive to climate change and variability, as well as land use practices (Kasischke et al., 2006; Soja et al., 2007; IPCC, 2007; Amiro et al., 2009; Flannigan et al., 2009; Oris et al., 2013; Kelly et al., 2013), they constitute a large source of variability in Arctic tropospheric composition.

Biomass burning plumes transported over the Arctic have been observed by ground-based Fourier transform infrared (FTIR) spectrometers (Yur'yanov et al., 2004, 2005; Viatte et al., 2013), measurements on aircraft (Paris et al., 2009; Warneke et al., 2009; Simpson et al., 2011; Hecobian et al., 2011; Parrington et al., 2013; O’Shea et al., 2013; Le Breton et al., 2013; Lewis et al., 2013), and satellites (Rinsland et al., 2007; Coheur et al., 2009; Tereszchuk et al., 2011, 2013). Model simulations and meteorological analyses also suggest pollution transport pathways to the Arctic (Eckhardt et al., 2003; Klonecki et al., 2003; Koch and Hansen, 2005; Stohl et al., 2006; Shindell et al., 2008; Thomas et al., 2013; Bian et al., 2013). However, our knowledge concerning transport, degradation mechanisms of NMHCs (Stavrakou et al., 2009), sources of Arctic pollution (Fisher et al., 2010), and emissions from fires (Akagi et al., 2011), remains incomplete, reflecting the heterogeneous and stochastic nature of these processes. Long-term and continuous measurements of Arctic tropospheric composition are therefore important for quantifying emissions from fire plumes transported from lower latitudes and improving the prediction of trace gas concentrations and variability in chemical transport model simulations. This would help in assessing the atmospheric impact of biomass burning pollution on the Arctic climate system.

To simulate fire emissions in chemical transport models, emission factors of various trace gases must be estimated with accuracy. Emission factors are highly variable however, because they depend on the types of vegetation burned, the combustion phase (smoldering and flaming), and atmospheric conditions at the time of the fire events (Paton-Walsh et al., 2005, 2008, 2010; Akagi et al., 2011; Hornbrook et al., 2011; Vigouroux et al., 2012). Within the past decade, measurements of emission factors of biomass burning species have led to a wide range of values, which may be due to the natural variability of the emissions and/or the discrepancies between sampling methods (laboratory, airborne, satellite, and ground-based measurements) that overestimate or underestimate the combustion phases (smoldering and flaming). The need for more measurements of HCN and NMHC emission factors has been stressed given the value of HCN as a biomass burning tracer (Li et al., 2003) and significant NMHC emissions from fires (Andreae and Merlet, 2001; Akagi et al., 2011; Paulot et al., 2011; Wiedinmyer et al., 2011).

We investigate pollution from biomass burning events that occurred in extratropical forests and were transported to the high Arctic with two sets of FTIR measurements, located at Eureka ( Nunavut, Canada, 80º05’N, −86º42’W) and Thule (Greenland, 76º53’N, −68º74’W). Seven tropospheric species (CO, HCN, C₂H₆, C₂H₂, CH₃OH, HCOOH, and H₂CO) released by biomass burning were monitored from 2008 to 2012. Complete descriptions of the methodologies and characterizations of the retrievals are found in Viatte et al. (2014). These species were selected because of their differing anthropogenic, biogenic, fossil fuel burning and biomass burning source fractions, as well as their widely differing lifetimes, sinks, and secondary production rates. From this diversity, we gain insight into chemistry and transport abilities of the Model for OZone And Related chemical Tracers, version 4 (MOZART-4, Emmons et al., 2010) and improve emission ratios. A significant number of observations inside fire plumes are identified in the data sets and used to derive emission ratios (and hence infer emission factors) of the target species. These measured emission ratios add new values to the sparse data set reported in the literature. The two sets of measurements are compared with MOZART-4 to assess the ability of this model to reproduce Arctic tropospheric chemical composition and its variability due to the long-range pollution transport from fires.
2 Observations and model data in the high Arctic

2.1 FTIR measurements at Eureka and Thule

We present measurements over 5 years of 7 tropospheric species in the high Arctic, CO, HCN, C$_2$H$_6$, C$_2$H$_2$, CH$_3$OH, HCOOH, and H$_2$CO, from 2008 to 2012. These time series are obtained from ground-based FTIR measurements performed at Eureka (80°05’ N, 86°42’ W, 0.61 km a.s.l., Eureka, Nunavut, Canada, Fogal et al., 2013) and Thule (76°53’ N, −68°74’ W, 0.23 km a.s.l., Greenland, Thule, Hannigan et al., 2009). The locations of the measurement sites are shown in Fig. 1. The high-resolution solar absorption spectrometers (a Bruker IFS 125HR at Eureka and a Bruker IFS 120M at Thule, both operated at a spectral resolution of 0.0035 cm$^{-1}$) are part of the international Network for the Detection of Atmospheric Composition Change (NDACC, http://www.ndsc.ncep.noaa.gov/, formerly NDSC, Kurylo, 1991; Kurylo and Zander 2001). These spectrometers measure spectra using two detectors (indium antimonide – InSb – or mercury cadmium telluride – MCT), a potassium bromide (KBr) beamsplitter, and a sequence of seven and eight narrow-band interference filters covering the 600–4300 cm$^{-1}$ and 750–5000 cm$^{-1}$ spectral ranges, at Eureka and Thule, respectively. A reference low-pressure hydrogen bromide (HBr) cell spectrum is recorded regularly with an internal globar source to characterize the instrument line shape (ILS) and monitor alignment of both instruments (Coffey et al. 1998). By using the LINEFIT software analysis (Hase et al., 1999), modulation efficiency and phase error are retrieved and can be included in the retrieval analysis (i.e., forward model).

In order to retrieve concentrations of these species from the recorded spectra, the optimal estimation method (OEM, Rodgers, 2000) has been applied using the new SFIT4 retrieval code (https://wiki.ucar.edu/display/sfit4/Infrared+Working+Group+Retrieval+Code,+SFIT). With the exception of the ILS and signal-to-noise ratio (SNR), which are specific to each instrument, we use the same methodology to analyze the Eureka and Thule measurements, i.e., homogenized micro-windows, the same spectroscopic parameters from the HITRAN 2008 database (Rothman et al., 2009), and the same a priori covariance matrices. For CO, HCN, and C$_2$H$_6$, retrieval parameters are based on the NDACC-IRWG standard parameter definitions (NDACC Infrared Working Group, http://www.acd.ucar.edu/irwg/). Details of the retrievals of the seven tropospheric species at Eureka are described in Viatte et al. (2014). A priori profiles of the target species are derived from the mean of 40 year runs from the Whole Atmosphere Community Climate Model, version 6 (WACCM, http://www2.cesm.ucar.edu/working-groups, Garcia et al., 2007; Eyring et al., 2007), for the two stations. Daily pressure and temperature profiles are from the National Center for Environment Prediction (NCEP, http://www.ncep.noaa.gov/). Monthly a priori water vapor profiles are taken from the WACCM output for each location. Our profiles are retrieved on 48 level altitude grids (from 0.61 to 120 km for Eureka, and from 0.23 to 120 km for Thule), and total and partial columns are then derived by vertically integrating these profiles.

Full error analysis has been performed for both data sets, as described in Rodgers (2000) and Rodgers and Connors (2003), and includes measurement noise error, smoothing error (expressing the limited vertical resolution of the retrieval), and forward model parameter error. Details about the seven tropospheric species error budget can be seen in section 2.6 of Viatte et al. (2014). Time series are obtained from February to October since the FTIR measurements require the sun as the light source. The seasonal cycles of CO, HCN, C$_2$H$_6$, C$_2$H$_2$, CH$_3$OH, HCOOH, and H$_2$CO are representative of their differing transport, emissions, lifetimes, and oxidation rates, and have been discussed in detail in Viatte et al. (2014) with reference to the Eureka data set.

The CO, HCN, and C$_2$H$_6$ total columns measured at Eureka and Thule from 2008 to 2012 are shown in the left and right panels, respectively, of Fig. 2. These species are considered to be biomass burning tracers, given their long lifetimes in the atmosphere of 52 days (Daniel and Solomon, 1998), 5 months (Li et al., 2003), and 80 days (Xiao et al., 2008) for CO, HCN, and C$_2$H$_6$, respectively. They exhibit strong
seasonal cycles, reflecting the importance of chemistry and transport processes in their Arctic budget. In addition to these cycles, simultaneous enhancements of the CO, HCN, and C$_2$H$_6$ total columns can be seen in the day-to-day variabilities, in both Eureka and Thule observations, such as in April and July 2008 (red circles, Fig. 2), and in August 2010 (green squares, Fig. 2). Enhancements of CO, HCN, and C$_2$H$_6$ total columns observed at Thule in June–July 2012 (olive triangles, Fig. 2) are not seen in the Eureka data set because there were no FTIR measurements at Eureka during this period. Some of these enhancements have already been attributed to biomass burning plumes transported to the Arctic. This has been done with aircraft measurements for the April 2008 (Warneke et al., 2009) and July 2008 events (Simpson et al., 2011) during the Arctic Research of the Composition of the Troposphere from Aircrafts and Satellites (ARCTAS) campaigns (Jacob et al., 2010; Hornbrook et al., 2011), and with ground-based FTIR measurements for the extreme August 2010 event (Viatte et al., 2013), as well as with the combination of numerous measurement platforms for the July 2011 event, during the Quantifying the impact of Boreal forest fires on Tropospheric oxidants over the Atlantic using Aircraft and Satellites (BORTAS) experiment (Palmer et al., 2013).

Figure 3 shows time series of C$_2$H$_2$, CH$_3$OH, HCOOH, and H$_2$CO total columns measured at Eureka (left panels) and Thule (right panels) from 2008 to 2012. These species have different lifetimes in the atmosphere, ranging from 2 weeks for C$_2$H$_2$ (Xiao et al., 2007) to less than 2 days for H$_2$CO (Coheur et al., 2007). Because of their possible chemical destruction during long-range transport to the Arctic, enhancements due to fire events are less significant than for the three main biomass burning tracers (Fig. 2), but are still present in the time series, as shown in August 2010 for Eureka (green squares, Fig. 3) and in August 2008 for Thule (red circles, Fig. 3). These species have also been measured by Atmospheric Chemistry Experiment-Fourier Transform Spectrometer (ACE-FTS, Tereszchuk et al., 2013) and Infrared Atmospheric Sounding Interferometer (IASI, Coheur et al., 2009) as well as aircraft measurements (Parrington et al., 2013, O’Shea et al., 2013) in boreal forest biomass burning plumes several days after their source emissions. Indeed, a recent study suggests that the physical age of one boreal plume in July 2011 is 1 to 5 days older than the photochemical age because of the presence of the pyrogenic aerosols that slow down the plume photochemistry for several days after the emission (Finch et al., 2014).

For various reasons, the number of days of observations out of the approximate 8-month sunlit portion of the year at these remote Arctic sites will vary year to year from as few as 15 to as many as 110. Often, days will have multiple observations. For the 5-year period (2008–2012), the average number of measurements per gas shown in Fig. 3 is 2149 for Eureka and 868 for Thule. Despite the difference in the number of FTIR measurements throughout the years between the Eureka and Thule data sets, the time series of the seven tropospheric species recorded at both stations exhibit similar seasonal cycles in terms of absolute values and temporal variabilities. We can exploit the accuracy of these FTIR retrievals, and the robustness of the multi-year observations, in the quantification of Arctic tropospheric composition and its variability. Super-imposed onto these seasonal cycles, the time series reveal short-term enhancements due to fire events that highlight the importance of the biomass burning long-range transport in the Arctic budget of NMHCs, which can affect air quality and climate in this region.

2.2 MOZART-4 description

MOZART-4 (Model for OZone And Related chemical Tracers, version 4), is a chemical transport model (CTM) developed jointly by the (US) National Center for Atmospheric
Research (NCAR), the Geophysical Fluid Dynamics Laboratory (GFDL), and the Max Planck Institute for Meteorology (MPI-Met) to simulate atmospheric chemical and transport processes. To assess the ability of MOZART-4 to reproduce the different seasonal cycles of the tropospheric species, as well as the day-to-day variabilities due to fire signatures, we used daily mean outputs for all of 2008 and a temporal resolution of 6 h within four time periods between 2008 and 2012 (Emmons et al., 2010) for comparison with the FTIR data sets. Those periods are (1) March to August 2008 to assess the model’s seasonal cycles, (2) August to October 2010 to evaluate biomass burning emissions of the model for the most extreme fire event, as well as (3) May to July 2011 and (4) June to July 2012 to focus the analyses on other fire events during summer periods.

For that specific model run, a comprehensive tropospheric chemistry, including 100 species, 160 kinetic, and 40 photolysis reactions, has been used. The simulations are driven by offline meteorological data from the Goddard Earth Observing System Model, version 5 (GEOS-5) and the Modern Era Retrospective analysis for Research and Applications (MERRA) at $0.5^\circ \times 0.6^\circ$ and $1.9^\circ \times 2.5^\circ$ resolutions with 56 vertical levels. Emissions are taken from the anthropogenic inventory created for the ARCTAS campaign by David Streets (Argonne National Lab, http://bio.cgerer.uiowa.edu/arctas/emission.html), which is based on several inventories, including the INTEX-B Asia inventory, the US Environmental Protection Agency (EPA) National Emission Inventory (NEI), the European Monitoring and Evaluation Programme (EMEP) inventory, as well as the Emissions Database for Global Atmospheric Research (EDGAR). For biomass burning emissions, we use the Fire INVentory from NCAR (FINN, Wiedinmyer et al., 2011). FINN is based on MODIS thermal anomalies and is available daily (https://www2.acd.ucar.edu/modeling/finn-fire-inventory-ncar); thus, MOZART-4 simulations do use daily fire emissions. Finally, biogenic emissions are calculated online for isoprene and terpenes, and offline for methanol, from the Model of Emissions of Gases and Aerosols from Nature (MEGAN) inventory (Guenther et al., 2012). At the time the simulations were performed, the significance of biogenic emissions of formic acid was not appreciated, and so were not included. In total, the model has a HCOOH emission of 3.7 Tg yr$^{-1}$, for which 1.1 Tg yr$^{-1}$ are for anthropogenic sources and 3.3 Tg yr$^{-1}$ for biomass burning. The estimate of biogenic HCOOH emissions in MEGAN-v2.1 is 3.7 Tg yr$^{-1}$ (Guenther et al., 2012), so inclusion of them would double the current MOZART-4 emissions.

3 Methods and results

3.1 Detection of biomass burning events with FTIR observations in the Arctic

We identify fire events in the FTIR time series by selecting all days that have simultaneous enhancements of the three main biomass burning tracers (CO, HCN, and C$_2$H$_6$). All measurements that lie beyond 3 standard deviations of the monthly mean total columns are considered as biomass burning indicators. This methodology was used in Viatte et al. (2013) and relies on the assumption that a smoke plume detected in the high Arctic has come from a relatively large fire and would have large emissions for several consecutive days.

With this methodology, ten biomass burning events have been identified as reaching Eureka (Table 1), and eight for Thule (Table 2), from 2008 to 2012. At least five fire events reached both sites almost simultaneously in March 2008, July–August 2008, July–August 2010, June–July 2011, and July 2012.

The number of events detected in the high Arctic appears correlated with the boreal forest temperature (Barrett et al., 2013). In summer 2009, only one event in June 2009 was detected over Eureka (Table 1). Low temperatures over the boreal forest (http://earthobservatory.nasa.gov/GlobalMaps/view.php?d1=MOD14A1_M_FIRE) are consistent with a smaller number of fire events detected at our sites. A recent study of FINN also confirms the smaller number of boreal fires in 2009 (Wiedinmyer et al., 2011, their Table 7).

In order to match the biomass burning candidate events identified in the time series with actual plumes, it is necessary to find the source fires and show that the plumes generated there are capable of travelling to the Arctic stations where they were observed. This is done by using various independent data sets.

2. The source region information in the form of “footprints”, from a time-reversed Lagrangian particle dispersion model, the Stochastic Time-Inverted Lagrangian Transport (STILT, Lin et al., 2003; Gerbig et al., 2003) model, also driven by GDAS meteorological fields. Trajectories were initialized at 0, 6, 12, and 18:00 UTC on 23 above-ground-height levels (ranging from 0.2 to 14.5 km). Each trajectory used 500 particles. Footprints from the different levels were combined as a weighted mean to create a single footprint that is representative of a column measurement. Weights were derived as the product of the pressure at the receptor.
Table 1. Fire events detected over Eureka with the date, days of measurements, vegetation type burned, fire source location, and travel time to the day of peak enhancement (represented in bold in the third column) used to calculate emission ratios.

multiplied by the instrument kernel density (which was linearly interpolated to the receptor height). The trajectories were run 30 days back in time.

In addition, we use AERONET aerosol optical depth (AOD) data measured at Eureka (O’Neill et al., 2008; Saha et al., 2010; http://aeronet.gsfc.nasa.gov/), when available, to detect simultaneous increases in fine-mode AOD and trace gas total columns, which is an additional fire event indicator. If these data all agree on a common origin for a plume, and the back-trajectories intersect that region during the same time, then the source of a biomass burning event has been successfully detected. Consistent results from these multiple data sets provide confidence in the attribution of trace gas enhancements to specific fire events.

Figure 4 shows an example of the source attribution and the travel duration of a plume that reached Eureka on 10 July 2008. We first note a simultaneous enhancement of the three main biomass burning tracer concentrations detected on 10 July 2008 at Eureka (see Fig. 5). As a priori information, STILT footprints are generated to show the source region influencing the atmospheric measurement at Eureka, which for that day is located in eastern Russia (light blue region inside the red box, Fig. 4a). Then, the FIRMS (Fire Information for Resource Management System, which provides MODIS hotspot data) map is used to verify that a significant fire event occurs in that specific region within a 10 day period (red dots in Fig. 4b). To assess the travel duration of that plume from the fire region to Eureka, an ensemble of HYSPLIT back-trajectories is generated, for several travel times, end times of the calculated trajectories, and air-parcel altitudes; e.g., for each biomass burning event detected at a specific time, we ran ten HYSPLIT back-trajectories for different altitudes ranging from 3 to 12 km, and modified the end time of these back-trajectories within 2 h of the observed enhancements. In Fig. 4c, air masses ending at Eureka at 5, 7, and 9 km (red, blue, and green lines, respectively) on 10 July come from the fire region (red box). And finally, the OMI aerosol index map is used to confirm the presence of a significant fire event in that region, as shown in Fig. 4d (colored area within the red box). A similar example of a fire source region and a travel time attribution can be seen in Viatte et al. (2013, Fig. 2) for the August 2010 event.

Using this methodology, four fire plumes were attributed to forest fires in Asia travelling for 7 to 9 days, and six from North America travelling between 5 and 8 days, for Eureka (Table 1). For Thule, three biomass burning plumes come
from Russia after 7 to 9 days of travel and five are from North America, travelling between 5 and 6 days (Table 2).

In addition, because fire emission composition depends upon, among other parameters, the type of biomass burned (Andreae and Merlet, 2001; Akagi et al., 2011), we assigned the vegetation type burned (boreal, temperate coniferous and grassland; Olson et al., 2001) for the different fire events based on the fire source region. This ensured the appropriate selection of the emission factor (EF) of CO needed to calculate the emission factors of the other species from the FTIR measurements of emission ratios (Sect. 3.2.2).

3.2 Evaluation of MOZART-4 in the Arctic

To assess the capacity of a model to estimate columns and variabilities of tropospheric species in the high Arctic, MOZART-4 was compared to the FTIR data sets. First, the general agreement between MOZART-4 and the measurements from 2008 to 2012 is discussed. Then, we focus on 2008 to analyze the model’s ability to reproduce the different seasonal cycles of the seven target species in the troposphere. Finally, we focus on the most extreme fire event detected in our measurements in August–October 2010, to discuss biomass burning emissions used in the model.

3.2.1 General comparisons between MOZART-4 and the FTIR data sets

For comparisons with the FTIR data sets, all MOZART-4 data within the closest grid box to both measurement sites, and within 3 h of each FTIR measurement, are selected. The FTIR and the MOZART-4 trace gas profiles are estimated over different altitude ranges, and with different vertical resolutions. For each molecule, the MOZART-4 profiles are combined with FTIR a priori profiles between 1.9 hPa (∼31 km) and 120 km. After extrapolating these model profiles onto the FTIR pressure grid, the model profiles are smoothed by convolution with the FTIR averaging kernels functions (corresponding to those specific measurements) following the equation (Rodgers and Connors, 2003)

\[ x_s = A(x - x_a) + x_a, \]  

where \( x_s \) is the smoothed MOZART-4 profile, \( A \) is the FTIR averaging kernel matrix and \( x_a \) is the FTIR a priori profile. Then, total and tropospheric partial columns (between 0 and 10.25 km) are recalculated from the smoothed model profiles. Typical FTIR averaging kernels of the seven tropospheric species can be seen in Viatte et al. (2014).

The FTIR retrievals have different vertical sensitivities for each species, characterized by the degrees of freedom for signal (DOFS), ranging on average over 4454 and 1747 measurements from 2.6 to 0.9 for CO and \( \text{H}_2\text{CO} \) at Eureka, respectively. For comparisons with the model, total or partial columns may be considered, given the DOFS for that species. For CO, HCN, and \( \text{C}_2\text{H}_6 \), DOFS can be used to separate tropospheric columns from stratospheric columns; therefore, tropospheric partial columns are considered in the comparison with the MOZART-4 data. For the others (\( \text{C}_2\text{H}_2 \), \( \text{CH}_3\text{OH} \), HCOOH, and \( \text{H}_2\text{CO} \)), the average DOFS are on order unity; therefore, only total columns are considered. However, these FTIR total columns that are the integrated abundance from the surface to 120 km are representative of the partial columns (0–30 km) because the FTIR retrievals of these troposphere species have almost no sensitivity above 30 km, and the tropospheric columns represent more than 90 % of the total columns (Viatte et al., 2014).

The results of comparing the MOZART-4 model and FTIR measurements over selected periods from 2008 to 2012 are shown in Tables 3 and 4, for Eureka and Thule, respectively. \( N \) is the number of measurements included in the comparison with MOZART-4. The coefficient of linear correlation \( (r) \) ranges from 0.35 to 0.93, where only two are less than 0.5 and the mean is 0.73. This shows strong correlations between the model and the measurements despite the larger size of the MOZART-4 box (1.9° × 2.5°) compared to our column measurements. Excellent correlations are found for CO, \( \text{C}_2\text{H}_4 \), and \( \text{C}_2\text{H}_2 \), for which \( r > 0.74 \) at both sites, confirming that the model explains at least 54 % of the atmospheric variability of these species in the Arctic. For HCN, the correlation is better at Eureka (\( r = 0.92 \)) than at Thule (\( r = 0.55 \)); however, the relative differences between the model and the measurements are small (6.7 ± 19.3 % for Eureka and 2.2 ± 19.5 % for Thule), highlighting the very good agreements between these data sets. Also, strong correlations are found for \( \text{CH}_3\text{OH} \) (\( r = 0.77 \) for Eureka and 0.62 for Thule). For HCOOH and \( \text{H}_2\text{CO} \), the correlations of 0.60 and 0.50, and 0.35 and 0.75, for Eureka and Thule, respectively, confirm the difficulty in modeling the concentrations of these short-lived species in the high Arctic, and highlight the relatively poor understanding of the sources and sinks of these two molecules.

The mean relative differences ((model-FTIR)/model) between MOZART-4 and CO and HCN partial columns are −2.9 ± 7.5 % and 6.7 ± 19.3 % for Eureka, and −2.5 ± 11.4 % and 2.2 ± 19.4 % for Thule, respectively. The 1-sigma standard deviations are larger than the means, confirming the agreement between the model data and the FTIR observations. For \( \text{C}_2\text{H}_6 \) partial columns, the mean relative differences of −50.3 ± 22.7 % and −54.1 ± 29.7 % for Eureka and Thule, respectively, are higher than the standard deviations. We infer that there is a significant underestimation of the \( \text{C}_2\text{H}_6 \) concentrations calculated by the model compared to the FTIR measurements. Our results confirm the underestimation of the model already highlighted with aircraft measurements during the ARCTAS campaign (Tilmes et al., 2011; Emmons et al., 2014). The \( \text{CH}_3\text{OH} \) mean relative differences of −23.3 ± 23.4 % and 1.9 ± 40.8 % for Eureka and Thule, respectively, show good agreement between MOZART-4 and the \( \text{CH}_3\text{OH} \) FTIR total columns, especially when considering the error bars of the measurements.
Table 3. Results of the 2008–2012 comparisons between MOZART-4 and the FTIR columns measured at Eureka for the seven species listed in the first column. The comparisons are made for the tropospheric columns (0.6–10.25 km) for CO, HCN and C₂H₆ and for the total columns (for the other gases). $N$ is the number of points included in the comparisons and $r$ is the coefficient of linear correlation. The relative differences (in percentage) are calculated as (model-FTIR)/model, and SD is the 1-sigma standard deviation around the mean difference. The last four columns are the slopes of the linear regression lines between MOZART-4 and FTIR along with their errors, the error bars in the FTIR total columns (in percentage), and the atmospheric lifetimes of the target species.

(~12%). For C₂H₂ and H₂CO total columns, the agreements are poor, with large standard deviations, and for HCOOH, the model did not include biogenic emissions, explaining the extreme differences.

Finally, the slopes (model vs. FTIR) are all less than 1, except for C₂H₂. This indicates that the model underestimates the columns relative to the FTIR data, suggesting that the model underestimates either emissions or transport of the seven tropospheric species in the high Arctic. It could also suggest that the model overestimates their chemical destructions in smoke plumes because of reduced photochemical activity due to aerosol scattering.

3.2.2 Comparisons of the FTIR and MOZART-4 seasonal cycles in 2008

The 2008 time series of daily mean CO, HCN, C₂H₆, C₂H₂, CH₃OH, and H₂CO total columns measured by the FTIRs at Eureka and Thule (Fig. 5, blue and green dots, respectively), and calculated by MOZART-4 at these two sites (Fig. 5, black and red dashed lines, respectively) are used to compare their seasonal cycles. This year was chosen because the April and July biomass burning events have been studied during the ARCTAS campaign (Jacob et al., 2010, and references therein). There are no CH₃OH measurements at Thule for 2008, because the optical filter used to measure this gas was installed in 2010. HCOOH time series are excluded here, because the MOZART-4 runs did not include online biogenic emissions, which have been shown to be a large source of HCOOH from the boreal forest (Stavrakou et al., 2012), and therefore the model does not capture HCOOH concentrations and variabilities, by at least an order of magnitude.

In winter, CO and C₂H₂ total columns estimated by MOZART-4 agree very well with the FTIR measurements, suggesting that transport is well represented in the model, since it is the major process controlling the Arctic budget of these long-lived gases in winter. However, for C₂H₆, which is also a long-lived tracer, the underestimation of its concentrations by MOZART-4 in winter confirms an underes-
Figure 6. Time series of CO, HCN, C$_2$H$_6$, C$_2$H$_2$, CH$_3$OH, and H$_2$CO total columns measured by the FTIRs at Eureka (blue) and Thule (green) and calculated by MOZART-4 at Eureka (black) and Thule (red) for the August 2010 fire event.

3.2.3 Comparisons of MOZART-4 and FTIR during the August 2010 fire events

To further assess the estimation of fire emissions in the model, we focus on the most extreme event in our data sets in August 2010. Details about the origin and transport of the plume from Russia through the Arctic are described in Viatte et al. (2013). Figure 6 shows the time series of CO, HCN, C$_2$H$_6$, C$_2$H$_2$, CH$_3$OH, and H$_2$CO total columns measured by the FTIR at Eureka (blue dots) and Thule (green dots) and calculated by MOZART-4 at Eureka (black dashed line) and Thule (red dashed line) for the August 2010 fire event.

Except for C$_2$H$_6$ and C$_2$H$_2$, total columns measured by the FTIR and calculated by the model are generally in agreement during this fire event. In addition, enhancements due to the fire plume recorded at both stations around 23 August are captured in the model. However, the amplitudes of these enhancements in MOZART-4, which reflect fire emissions in the model, seem too low for all the gases, except for CH$_3$OH and H$_2$CO. For CO, fire emissions in MOZART-4 are too low, as seen previously (Sect. 3.2.2). For C$_2$H$_6$ and C$_2$H$_2$, concentrations calculated by the model are biased low, indicating missing sources. For CH$_3$OH, fire emissions estimated in the model seem appropriate.

3.3 Estimation of emissions from fires with FTIR measurements

3.3.1 Correlation between CO and the other trace gases

In order to estimate emissions from fires, all fire-affected measurements identified in the biomass burning events reaching the two Arctic sites (Tables 5 and 6) from 2008 to 2012 are used. Concentrations within smoke plumes vary rapidly with time, so emission factors are derived by measuring the emission ratio of the target chemical species relative to a reference species, which is often CO$_2$ or CO (Hurst et al., 1994). We use CO as the reference because these measurements are most sensitive to plume enhancements. Because the emission ratio is not measured at the source of the fire, the downstream measurements here more accurately yield an “enhancement ratio” (EnhR). These ratios are derived from the regression slopes of a given trace gas total column versus that of CO, for each fire event. Since the spectral acquisitions require the use of optical filters, and spectra are taken sequentially, we selected all CO measurements made within a 20 min interval of the target gas measurement in order to calculate enhancement ratios. Uncertainties in this tracer/tracer enhancement ratio method are small if both tracers have long atmospheric lifetimes relative to plume travel durations between the fire source and the measurements. Because the emission ratio is not measured at the source of the fire, the downstream measurements here more accurately yield an “enhancement ratio” (EnhR). These ratios are derived from the regression slopes of a given trace gas total column versus that of CO, for each fire event. Since the spectral acquisitions require the use of optical filters, and spectra are taken sequentially, we selected all CO measurements made within a 20 min interval of the target gas measurement in order to calculate enhancement ratios. Uncertainties in this tracer/tracer enhancement ratio method are small if both tracers have long atmospheric lifetimes relative to plume travel durations between the fire source and the measurements. In addition, errors in transport and plume altitude are also minimized, since all tracers are expected to be mixed and transported in the same air masses. These assumptions constitute the main limitation of this approach (Yokelson et al., 2013).

Figures 7 and 8 show the correlation plots of the total columns of the target species relative to CO, for all fire events (represented by different colors) detected at Eureka and Thule, respectively. For Eureka (and Thule), the en-
Figure 7. Scatterplots of the total columns of the target species (HCN, C$_2$H$_6$, C$_2$H$_2$, CH$_3$OH, HCOOH, and H$_2$CO) relative to CO for the ten fire events detected at Eureka (2008–2012).

Figure 8. Scatterplots of the total columns of the target species (HCN, C$_2$H$_6$, C$_2$H$_2$, HCOOH, and H$_2$CO) relative to CO for the eight fire events detected at Thule (2008–2012).

Enhancement ratios are estimated from each biomass burning event, with 313 (136), 321 (274), 205 (137), 228 (-), 202 (120), and 298 (149) pairs of CO columns with HCN, C$_2$H$_6$, C$_2$H$_2$, CH$_3$OH, HCOOH, and H$_2$CO columns, respectively. Given the small number of CH$_3$OH FTIR observations at Thule, we did not estimate its enhancement ratio here (see below).

The correlations of HCN, CH$_3$OH, HCOOH, and H$_2$CO total columns with CO using all of the fire data sets (all colors combined, Figs. 7 and 8) are not linear, since these species have different atmospheric lifetimes from CO (Viatte et al., 2014). In contrast, CO, C$_2$H$_6$, and C$_2$H$_2$ have common sinks and sources, so their columns are expected to be correlated throughout the year. Except for H$_2$CO, correlations of the fire species with CO in the individual fire plumes (individual colors, Figs. 7 and 8) exhibit linear patterns. This confirms that the target gases are transported in the same air masses from the emitted fire sources. For H$_2$CO, the correlations with CO are not clearly linear inside fire plumes. However, the measured total columns are significantly enhanced (up to $4.5 \times 10^{15}$ molecules cm$^{-2}$) in August 2008 at Thule, in August and July 2010 at Eureka and Thule, respectively, in June 2011 and July 2011 at both sites, as well as in July 2012 at Thule. Given the back-trajectory analyses, these enhanced H$_2$CO columns recorded in the high Arctic are correlated with extreme fire events in the boreal forest during summer.

For each event, the slopes of the regression lines are taken as the enhancement ratios of the species emitted by fires. The correlations are obtained by linear regression using the method of York et al. (2004), which takes into account uncertainties in both ordinate and abscissa variables. The total uncertainty for the regression slopes is calculated by quadrature addition of the fit uncertainties and the measurement uncertainties. Those values are summarized in Tables 5 and 6 for Eureka and Thule, respectively. $N$ is the number of pairs (between the target species vs. CO) used to estimate the enhancement ratios, $r$ is the correlation coefficient of the linear regression, and EnhR is the enhancement ratio given by the slope of the regression line for each fire event. To assess changes due to photochemistry during plume aging (Akagi et al., 2012), the enhancement ratio corrected by the travel time of the plume (ER) has been included in Tables 5 and 6. If less than six pairs are measured in a fire plume, the enhancement ratios are not estimated from this event, i.e., C$_2$H$_2$ measurements at Eureka in July 2010. No error weighting was performed according to the number of points.

The correlation coefficients between HCN and CO total columns are on average 0.84 and 0.79 for the Eureka and Thule data sets, respectively (last columns in Tables 5 and...
Table 5. Correlation between each trace gas and CO inside the smoke plumes detected over Eureka. $N$ is the number of points, $r$ is the coefficient of linear correlation and EnhR is the enhancement ratio, which is the slope derived from the correlation. For all gases except H$_2$CO, ER represents the corrected enhancement ratios from travel time calculated only if the linear correlation coefficient ($r > 0.6$) and the number of points ($N > 6$). * Values excluded from the mean calculations.

6). Good correlations between C$_2$H$_6$ and CO total columns ($r = 0.81$ on average for both data sets) also confirm that the selected measurements, listed in Tables 1 and 2, were made inside fire plumes. The means of the correlation coefficients between C$_2$H$_2$ and CO total columns inside plumes are 0.78 and 0.80, for Eureka and Thule, respectively. For CH$_3$OH, the average of the coefficients of correlation is 0.65 at Eureka. The HCOOH total columns are also well correlated with CO inside the plumes, given the average values of $r$ of 0.79 and 0.58 at Eureka and Thule, respectively. However, the July 2010 event has a negative correlation coefficient between HCOOH and CO at Thule, but the small numbers of points ($N = 6$ and 8, for Eureka and Thule, respectively) are too low to draw significant conclusions. The mean correlation coefficients between the H$_2$CO and CO total columns are similar: $r = 0.41$ and 0.40 at Eureka and Thule, respectively. Given the short atmospheric lifetime of this molecule and the fact that the measurements are not performed at the source of the fires, H$_2$CO could have been destroyed in the atmosphere while being transported through the Arctic. However, the wide ranges of the $r$ values, from 0.08 to 0.90 at Eureka in March 2008 and July 2012, and from 0.34 to 0.93 in August 2008 and June 2011 at Thule, suggest a possible secondary production of H$_2$CO in some atmospheric smoke plumes, where $r$ is high. Young and Paton-Walsh (2011) also show that concentrations of H$_2$CO within Australian smoke plumes increase during the first day of travel before declining 2 days after they were emitted.

The enhancement ratios are expected to vary with the travel time of the plumes from their source to the measurement site (see the last columns in Tables 1 and 2), especially for short-lived species, because of their faster atmospheric destruction (via photochemistry, oxidation, as well as dry and wet depositions) compared to CO. However, the mean enhancement ratios of the target gases over all fire events are comparable for the two sites. For instance, the Eureka and Thule mean enhancement ratios of HCN, over all biomass burning events, are 0.00334 ± 0.00094 (1-sigma standard deviation) and 0.00429 ± 0.00245, respectively (last columns in Tables 5 and 6). In addition, the enhancement ratios of HCN, C$_2$H$_6$, and C$_2$H$_2$ estimated from the extreme fire event of August 2010 are very similar: 0.00563 and 0.00650 for HCN, 0.01019 and 0.01235 for C$_2$H$_6$, and 0.00189 and 0.00191 for C$_2$H$_2$, for Eureka and Thule, respectively.
3.3.2 Calculation of emission ratios (ERs) and emission factors (EFs)

In models, fire emissions are often specified by using emission ratios relative to a reference species, typically CO, which correspond to measured ratios at the source of the biomass burning event. Those emission ratios are equal to the enhancement ratios corrected for the travel duration of the plume. By considering the different lifetimes of the molecules (Table 3, last column) as well as the plume travel times to reach Eureka and Thule (last columns of Tables 1 and 2), we calculated the decay rates of each species to obtain the percentage of their initial values remaining when they were measured. This allows the measured enhancement ratios to be corrected to the equivalent emission ratios (Paton-Walsh et al., 2005; Akagi et al., 2011; Hornbrook et al., 2011). More details regarding this correction are found in Viatte et al. (2013). Since the uncertainty in the correction is small compared to other uncertainties, our equivalent emission ratios can be compared to other emission ratios found in the literature. For comparison with previous studies, our equivalent emission ratios have been converted into equivalent emission factors using Andreae and Merlet (2001):

$$\text{EF}_x = \text{ER}_{x/\text{CO}} \times (\text{MW}_x/\text{MW}_\text{CO}) \times \text{EF}_\text{CO},$$

(2)

where $\text{EF}_x$ is the emission factor for trace gas X in g of gas per kg of dry biomass burnt; $\text{ER}_{x/\text{CO}}$ is the molar emission ratio of trace gas X with respect to CO; $\text{MW}_x$ is the molecular weight of trace gas X; $\text{MW}_\text{CO}$ is the molecular weight of CO; and $\text{EF}_\text{CO}$ is the emission factor of CO.

In this study, values of $\text{EF}_\text{CO}$ of $127 \pm 45 \text{ g kg}^{-1}$ and $107 \pm 37 \text{ g kg}^{-1}$ for dry matter based on Akagi et al. (2011) and Andreae and Merlet (2001), respectively, are taken as the emission factors for CO for boreal and extratropical forests, since this is the fuel type of the relevant source fires (vegetation type columns in Tables 1 and 2). Uncertainties in the measured EF are calculated by taking into account the large uncertainty in the CO emission factor (more than 35 %) and the uncertainty in the mean calculated regression slope (33.6, 54.0, 49.5, 32.2 and 22.8 % for HCN, C₂H₆, C₂H₅, CH₃OH, and HCOOH at Eureka, respectively, and 43.5, 33.1, 52.5, and 16.3 % for HCN, C₂H₆, C₂H₅, and HCOOH, respectively, at Thule), as well as the total uncertainties in the retrievals (3.1, 10.5, 14.3, 22.5, 12.3, and 17.0 % for CO, HCN, and HCOOH at Eureka, respectively, and 43.5, 33.1, 52.5, and 16.3 % for HCN, C₂H₆, C₂H₅, and HCOOH, respectively, at Thule).
C₂H₂, C₂H₆, CH₃OH, and HCOOH, respectively; Viatte et al., 2014, their Table 3), all combined in quadrature (Paton-Walsh et al., 2005). Total uncertainties in EFs are 49.2, 67.3, 61.8, 48.7, and 42.3% for HCN, C₂H₆, C₂H₂, CH₃OH, and HCOOH, at Eureka, respectively, and 57.5, 48.7, 63.8, and 46.5% for HCN, C₂H₆, C₂H₂, and HCOOH, at Thule, respectively. Because the uncertainties in the FTIR H₂CO retrievals are high (~27%) and the transport times of the plumes to the Arctic exceed its atmospheric lifetime (which is less than 2 days), emission ratios of H₂CO have not been estimated in this study.

Our corrected enhancement ratios (i.e., equivalent emission ratios, “ER” in Tables 5 and 6) have been converted into equivalent emission factors using Eq. (2). Only enhancement ratios calculated from more than six pairs (N>6), and satisfying a coefficient of correlation of more than 0.6 (r>0.6), are taken into account to estimate emission factors. The means of equivalent emission ratios and emission factors (calculated using EF₃₄CO for the extratropical forest) estimated from FTIR measurements performed at Eureka and Thule are summarized in Table 7.

Figure 9 shows the emission factors calculated from FTIR measurements performed at Eureka (cyan) and Thule (green), using EF₃₄CO of Andreae and Merlet (2001) for extratropical forest. Error bars correspond to the uncertainty in the CO emission factor and the uncertainty in the calculated regression slope, as well as the total uncertainties in the retrievals, all combined in quadrature.

In order to compare our results with others, emission factors from two compilations of data (Andreae and Merlet, 2001; Akagi et al., 2011) for extratropical and boreal forests have been selected. These studies contain a comprehensive set of emission factors from the burning of numerous vegetation types derived from various measurement platforms. Figure 10 shows the emission factors calculated from the FTIR measurements (in blue and cyan), along with the emission factors found in the compilation studies of Akagi et al. (2011) (red) and Andreae and Merlet (2001) (pink). The blue color corresponds to the emission factors calculated using the EF₃₄CO for the boreal forest from Akagi et al. (2011), whereas the cyan color corresponds to the values of EF₃₄carbon calculated using the EF₃₄CO for the extratropical forest from Andreae and Merlet (2001).

Our EF₃₄NO are lower than the two mean values reported in the literature. The sources and sinks of HCN are not well known. Our EF₃₄CH₃O agree well, within combined error, with the mean value reported by Akagi et al. (2011) and are higher than the mean value reported in the earlier study of Andreae and Merlet (2001). The emission factors of C₂H₂ estimated from the FTIR measurements are in excellent agreement with the mean values reported in both compilation studies. Our EF₃₄HCOOH are in agreement with the mean value from Akagi et al. (2011) and are higher than the mean value reported by Andreae and Merlet (2001), suggesting that CH₃OH emissions from fires are higher than previously thought. Finally, our EF₃₄HCOOH are significantly higher than the values reported in the more recent compilation study of Akagi et al.
al. (2011), but agree well with the mean value reported in 2001 (Andreae and Merlet, 2001). This may suggest that fires from the extratropical forest emit relatively large amounts of HCOOH, or it may reflect a local biogenic component in our measurements.

4 Summary and conclusions

The frequency and intensity of biomass burning are strongly linked to climate change, and constitute a large source of the variability in Arctic tropospheric composition. We performed FTIR measurements of seven important biomass burning species (CO, HCN, C₂H₆, C₂H₂, CH₃OH, HCOOH, and H₂CO) at two high Arctic sites, Eureka and Thule, from 2008 to 2012. We focused on these species for several reasons. (1) There remain numerous gaps in the available tropospheric observational data sets, especially at high latitudes. (2) Since these species exhibit different source fractions (anthropogenic, biogenic, fossil fuel burning, and biomass burning), as well as different lifetimes, the comparison of our new data sets with chemical transport model simulations can help identify issues in the model that can be addressed to improve their estimations of trace gas concentrations and temporal variations, as well as transport processes in the high Arctic. (3) All these biomass burning products are measured almost simultaneously using the FTIR technique, so we derived emission factors to add new values to the relatively sparse data sets in the literature.

Those new data sets of tropospheric species recorded at both stations exhibit similar seasonal cycles, in terms of absolute values and temporal variabilities. In addition, ten and eight fire events were identified at Eureka and Thule, respectively. These highlight the importance of the biomass burning long-range transport in the Arctic budget of NMHC, which can affect air quality and climate in this region. This may have a continued and increasing effect in a warming climate and sensitive Arctic ecosystem.

The two sets of measurements were compared with MOZART-4 to assess (1) the general agreement (2008–2012), (2) the model simulations of the different seasonal cycles (with the 2008 year), and (3) fire emissions in the model. Correlations between MOZART-4 and FTIR total columns are strong (r ranges from 0.35 to 0.93). The mean relative differences between MOZART-4 and the CO and HCN measurements confirm the good agreement between the model data and the FTIR observations. In winter, CO and C₂H₂ total columns estimated by MOZART-4 agree well with the FTIR measurements, suggesting that transport is well represented in the model, since it is the major process controlling the Arctic budget of these long tropospheric lifetime gases. However, for C₂H₆, the low columns estimated in winter by MOZART-4 confirm an underestimation in its emissions in the model. For HCN, the good agreement in winter also confirms that transport is well reproduced. In spring and summer, however, the overestimation of the model columns suggests that loss processes for HCN are missing. Finally, the CH₃OH total columns show good agreement between MOZART-4 and the FTIR data set at Eureka.

In order to estimate emissions from fires, all fire-affected spectra recorded inside smoke plumes were used to calculate the enhancement ratios relative to CO. Very good correlations with CO are found inside smoke plumes in the Arctic, confirming the common fire origins and transport pathways. CO and H₂CO total columns are well correlated (r > 0.9) inside fire plumes transported in June 2011 to Thule and in July 2012 to Eureka, suggesting a possible secondary production of H₂CO in atmospheric smoke plumes. The enhancement ratios were used to derive equivalent emission ratios from which emission factors were calculated using an assumed emission factor for CO. The means of emission factors estimated with the two FTIR data sets are 0.40 ± 0.21 g kg⁻¹ for HCN, 1.24 ± 0.71 g kg⁻¹ for C₂H₆, 0.34 ± 0.21 g kg⁻¹ for C₂H₂, and 2.92 ± 1.30 g kg⁻¹ for HCOOH. The emission factor for CH₃OH estimated at Eureka is 3.44 ± 1.68 g kg⁻¹. These measurements add new observations to the sparse data set of emission factors that have been reported and compiled in the literature.

An extension of this work would be to compare the FTIR measurements to the CAM-chem model (Lamarque et al., 2010), which has online MEGAN biogenic emissions for
many species, such as methanol and formic acid, to assess how this improves the comparison compared to MOZART-4.
