Abstract. It was recently found that spectral solar incident flux (SIF) as a function of the ultraviolet wavelengths exhibits \(1/f\)-type power-law correlations. In this study, an attempt was made to explore the residues of the SIF with respect to the Planck law over a wider range of wavelengths, from 115.5 to 629.5 nm. Using spectral, Haar and Detrended Fluctuation analyses, we show that over the range from 10–20 nm to the maximum lag (\(\approx 500\) nm), the SIF residues have a scaling regime with fluctuation exponent \(H \approx 0.37\) but with high intermittency (\(C_1 \approx 0.16\), multifractal index \(\alpha \approx 1.7\)) and spectral exponent \(\approx 1.46\). Over the shorter wavelengths range we found on the contrary low intermittency (\(C_1 \approx 0\)) with spectral exponent \(\approx 1\) and \(H \approx 0\).

1 Introduction

As is well known, electromagnetic radiation is continuously emitted by every physical body. This radiation is described by Planck’s law near thermodynamic equilibrium at a definite temperature. There is a positive correlation between the temperature of an emitting body and the Planck radiation at every wavelength. As the temperature of an emitting surface increases, the maximum wavelength of the emitted radiation increases too. Smith and Gottlieb (1974) re-examined the subject of photon solar flux and its variations vs. wavelength and showed that variations in the extreme ultraviolet (UV) spectrum and in the X-ray of solar flux may reach high orders of magnitude causing significant changes in the Earth’s ionosphere, especially during major solar flares (Kondratyev et al., 1995; Kondratyev and Varotsos, 1996; Ziemke et al., 2000; Varotsos et al., 2001; Melnikova, 2009; Tzanis et al., 2009; Xue et al., 2011; Cracknell et al., 2014).

Solanki and Unruh (1998) proposed simple models of the total solar irradiance variations vs. wavelength showing that variations on solar flux are mainly caused by magnetic fields at the solar surface. Solar observations may be reproduced by a model of three parameters: the quiet Sun, a facular component and the temperature stratification of sunspots.

Tobiska et al. (2000) developed a forecasting solar irradiance model, called SOLAR2000, covering the spectral range of 1–1000 000 nm. Using this tool, the authors attempted to describe solar variation vs. wavelength and through time from X-ray through infrared wavelengths, in order to predict the solar radiation component of the space environment.

Very recently, Varotsos et al. (2013a, b) suggested the existence of strong persistent long-range correlations in spectral space of the solar flux fluctuations for UV wavelengths in the range 278–400 nm. More precisely, by applying the detrending fluctuation analysis (DFA) to the initial SIF vs. UV wavelengths data set, power-law correlations of the type \(1/f\) were found pointing to a scaling feature in the UV spectral domain.

However, Varotsos et al. (2013a) tried to formulate the above-shown finding, i.e., that the solar spectral irradiance obeys \(1/f\) power-law as a function of UV wavelength, using the well-known Planck’s law: \(I(\lambda, T) = \frac{2h\nu^2}{\lambda^5(e^{\frac{2h\nu}{kT}} - 1)}\) which, in the limit of small wavelengths tends to the Wien approximation: \(I(\lambda, T) = \frac{2h\nu^2}{2\pi^2} e^{-\frac{2h\nu}{kT}}\), where \(I(\lambda, T)\) is the amount of energy emitted at a wavelength \(\lambda\) per unit surface area per unit time per unit solid angle per unit wavelength, \(T\) is the

Published by Copernicus Publications on behalf of the European Geosciences Union.
temperature of the black body, \( h \) is Planck’s constant, \( c \) is the speed of light, and \( k \) is Boltzmann’s constant. By applying the DFA method on the various values of \( I(\lambda, T) \), Varotsos et al. (2013a) showed that the calculated \( I(\lambda, T) \) values do not obey the \( 1/f \)-type scaling vs. \( \Delta \lambda \) (i.e., for fluctuations in \( I(\lambda, T) \) over a range \( \Delta \lambda \) in wavelength). Thus, the latter may reflect a scaling in its fluctuations which might be related to the complex physical processes taking place at the solar atmosphere (e.g. see Avrett and Loeser, 2008, and references therein).

In the present study, focusing on these fluctuations, we examine whether the \( 1/f \) scaling feature is apparent in a wider spectrum of SIF including both UV and visible spectrum, namely for wavelengths (WL) between 115.5 and 629.5 nm.

2 Data and analysis

As mentioned above, the solar incident flux data for WL ranging from 115.5 to 629.5 nm with a step of 1 nm were analyzed. The spectrophotometric data of spectral extraterrestrial solar flux have been taken from the book by Makarova et al. (1991) (see also Makarova et al., 1994; Melnikova and Vasilyev, 2005). Figure 1a depicts SIF values for the wavelength range of 115.5–629.5 nm. The principal feature shown in this figure is the existence of apparent non-stationarities vs. WL into the solar spectral distribution and the strong upward trend up to about 450 nm. The detrending of this data set was accomplished (Fig. 1a) by applying the Planck formula \( B_1 \left( \frac{b_1}{\lambda} \right)^5 / \exp \left( \frac{b_1}{\lambda} \right) - 1 \) with \( b_1 = 2486.4 \) nm based on the Sun’s effective temperature (\( T_{\text{sun}} = 5778 \) K) reported by NASA (http://nssdc.gsfc.nasa.gov/planetary/factsheet/sunfact.html) and the derived parameter was found to be \( B_1 = 85.8 \pm 0.7 \) (0.82 \%) mWm\(^{-2}\)nm\(^{-1}\). Hereafter, we focus on these detrended SIF data (i.e. the residuals with respect to the Planck function) which are shown with the blue line in Fig. 1a; these are the deviations from a pure black body spectrum. To estimate the scaling exponents, we first applied the well-known DFA method (Peng et al., 1994; Weber and Talkner, 2001; Varotsos, 2005; Varotsos et al., 2008, 2009, 2011, 2012; Sarlis et al., 2010; Skordas et al., 2010; Efstathiou and Varotsos, 2010, 2013; Efstathiou et al., 2011; Chattopadhyay and Chattopadhyay, 2014).

Furthermore, we calculated the power spectrum for the detrended SIF data set using the Fast Fourier Transform (FFT) algorithm as well as the maximum entropy method (MEM) (Hegger et al., 1999).

A brief description of DFA-\( n \) tool may be given as follows:

1. Consider the SIF data set \( x(i) \) of length \( N \) which is integrated over WL. Therefore, the integrated data set, \( y(i) \), consists of the following points:

\[
y(1) = x(1), \quad y(2) = x(1) + x(2), \ldots, \quad y(i) = \sum_{k=1}^{i} x(k).
\]

2. We split the integrated data set into non-overlapping boxes of equal length, \( \tau \). In each box, a best polynomial local trend (of order \( n \)) is fitted in order to detrend the integrated profile (by subtracting the locally fitted trend).

3. The root mean square fluctuations \( F_d(\tau) \) of this integrated and detrended profile is calculated over all scales (box sizes). For each interval, the detrended fluctuation \( F_k \) within the \( k \)th box (Kantelhardt et al., 2002) is defined by:

\[
F_k^2(\tau) = \frac{1}{\tau} \sum_{i=k+1}^{(k+1)\tau} [y(i) - z(i)]^2,
\]

\[
k = 0, 1, 2, \ldots \quad \left( \frac{N}{\tau} - 1 \right),
\]

where \( z(i) \) is the corresponding polynomial least-square fit to the \( \tau \) data contained and (Peng et al., 1994):

\[
F_d^2 = \frac{1}{(N/\tau) - 1} \sum_{k=0}^{(N/\tau)-1} F_k^2(\tau).
\]

In case the signals involve scaling, a power-law behavior for the root mean square fluctuation function \( F_d(\tau) \) is observed:
\[ F_d(\tau) \sim \tau^a, \] (4)

where \( a \) is the scaling exponent, a self-affinity parameter that represents the long-range power-law correlation (Aullos and Ivanova, 2001).

The above is fine for the nonintermittent, quasi-Gaussian case, but in the general (multifractal) case – which is of interest here – it is more convenient to define the mean fluctuation of the running sum \( F_d' \) using the mean \( F_d' = \frac{1}{(N/\tau)} \sum_{k=0}^{(N/\tau)-1} F_k(\tau) \) in Eq. (3) rather than \( F_d \) which is the RMS fluctuation of the running sum. Defining the mean fluctuation exponent \( a' \) by: \( F_d' \sim \tau^{a'} \), we find that in the quasi Gaussian case, \( a' = a \) = the usual Hurst exponent \( H \), although if we want the \( H \) of the process (rather than its sum), we must subtract unity: \( a = a' = 1 + H \). In the general multifractal case, we can define the fluctuations of the process by \( F_d'/\tau \) and we can quantify the statistics via the \( q \)th order structure function \( S_q(\tau) = (\langle F_d'/\tau \rangle^q \sim \tau^{\xi(q)} \). We see that \( a = 1 + \xi(2)/2 \) whereas \( a' = 1 + \xi(1) \). Finally, we can decompose \( \xi(q) \) into linear and convex parts: \( \xi(q) = q H - K(q) \) where \( K(q) \) characterizes the intermittent, multifractal contribution. With this, we obtain \( a = 1 + H - \xi(2)/2 \), \( a' = 1 + H \); the two are equal when \( K(q) = 0 \). In this special case where the process is quasi-Gaussian – unlike the general multifractal case – a single exponent \( a \) can only be sufficient to characterize the scaling of the process. If the process is exactly Gaussian, when \( 0 < a < 1 \), \( -1 < H < 0 \), the process is a fractional Gaussian noise (fGn) and when \( 1 < a < 2 \) \( (0 < H < 1) \), it is a fractional Brownian motion (fBm).

For uncorrelated quasi Gaussian data, the scaling exponent is \( a = 1/2 \), \( (H = -1/2) \). Scaling generally implies the existence of long range statistical dependencies. However in the special Gaussian case, when \( a = 1/2 \), then one has a Gaussian white noise and there are no long range dependencies. However, the fact that \( a = 1/2 \) can only be used to infer an absence of long range dependencies if it can be shown that the process is indeed quasi-Gaussian (in practice it has to be shown that it is not significantly intermittent, i.e. multifractal) in a certain range of \( \tau \) values. If \( 0 < a < 0.5 \) (and if the data set is nonintermittent), power-law anticorrelations are present (antipersistence). When \( 0.5 < a \leq 1.0 \) (and if again the data set is nonintermittent), then present-long range power-law correlations prevail (the case \( a = 1 \) corresponds to the so-called \( 1/f \) noise) (Weber and Talkner, 2001).

Finally, the scaling properties of SIF-WL data set were also studied using Haar fluctuation analysis (Lovejoy and Schertzer, 2012a, b). In the DFA method above, fluctuations are defined by the standard deviation of the differences of the polynomial regressions of the integrated process (the \( F_k \); to obtain the fluctuation of the series rather than its sum, we must divide by \( \tau \): \( F_k(\tau)/\tau \). In the more general framework of wavelets, they are defined by convolutions with respect to (almost) arbitrarily shaped mother wavelets. While both DFA and wavelet based fluctuations give essentially the same accuracy when used for estimating scaling exponents (such as \( H \), see e.g., Lovejoy and Schertzer, 2012a), if the wavelet is appropriately chosen, then the interpretation of the fluctuations becomes very simple so that the analysis can be much more generally (i.e. when there is more than a single scaling regime, or even if there is no scaling at all). The difficulty in interpreting the DFA fluctuations is the reason why in published plots, units are typically not even provided for the fluctuation axes. In contrast, for the series \( x(t) \) the simple (and indeed first wavelet) Haar fluctuations \( \Delta x(\Delta t) \) are defined simply as the difference between the averages of a series over the first and second halves of an interval \( \tau = \Delta t: \Delta x(\Delta t) = 2[\sum_{c\prime < t < c + \Delta t} x(t') - \sum_{c + \Delta t/2 < t' < c + \Delta t} x(t')]/\Delta t \) (\( \Delta t \) is the time scale, time lag, it is the same as the \( \tau \) in the DFA method). They have the property that in regions where \( -1 < H < 0 \), they can be interpreted simply as resolution \( \Delta t \) anomalies. Whereas in regions where \( 0 < H < 1 \), they can be interpreted as differences: \( \Delta x(\Delta t) = [x(t + \Delta t) - x(t)] \). Once the Haar fluctuations have been determined one can characterize them statistically by taking averages of various powers \( q \); the generalized \( q \)th order structure function \( S_q(\Delta t) = \langle \Delta x(\Delta t)^q \rangle \), where the symbol \( \langle \cdot \rangle \) stands for ensemble averaging. In a scaling regime, \( S_q(\Delta t) \sim \Delta t^{\xi(q)} \), where the exponent \( \xi(q) = q H - K(q) \) and \( K(q) \) is in general non-linear and convex and characterizes the intermittency (satisfying \( K(1) = 0 \)). In the previous DFA discussion, the process was assumed to be quasi-Gaussian, this implies the assumption \( K(q) = 0 \) (the DFA fluctuations are of course valid without this restriction). For universal multifractals (e.g. Schertzer and Lovejoy, 1987),

\[ K(q) = C_1 \frac{(q^\alpha - q)}{(\alpha - 1)}, \] (5)

where \( C_1(\geq 0) \) indicates the scaling intermittency and \( \alpha (0 \leq \alpha \leq 2) \) – not to be confused with the DFA exponent – is the multifractality index (the Lévy index of the generator). Note that in the DFA literature, sometimes the exponent \( h(q) = 1 + \xi(q)/q \) is introduced, the motivation being that in quasi Gaussian process, \( K(q) = 0 \) so that \( h(q) = \) constant (independent of \( q \)). However, when \( C_1 \neq 0 \) this leads to \( h(q) \rightarrow \infty \) as \( q \rightarrow 0 \) for all \( \alpha \leq 1 \). Since \( \alpha = 0 \) is the monofractal limit, we obtain \( h(0) = \infty \) which is neither intuitive nor convenient.

3 Discussion and results

Varotsos et al. (2013a) studying the high-resolution observations of SIF reaching the ground and the top of the atmosphere, suggested that SIF vs. UV WL exhibits \( 1/f \)-type power-law correlations. This result was derived by applying the DFA method on the SIF data set obtained from the Villard St. Pancrace station of the Lille University of Sciences and
Technology and was based on the slope (i.e., $a = 1.02 \pm 0.02$), hence $H = 0.02 \pm 0.02$ of the log–log plot of the root mean square fluctuation function of SIF vs. the WL segment size $\tau \equiv \Delta t = \Delta \lambda$.

In the present study, the scaling dynamics of a wider spectrum of SIF vs. WL data set was studied, for wavelengths between 115.5 and 629.5 nm. Firstly, DFA-$n$ seemed to take care of the trends revealing a DFA-exponent close to unity (after DFA-1), as shown in Fig. 1b.

In the following we plotted the power spectral density (using FFT) of the detrended SIF data set. The derived power spectral density showed that the power-law fitting gives an exponent $\beta = 0.99 \pm 0.08$ (see also below and Fig. 2). We can see that the slope inferred from the Haar analysis (below, $\beta = 1.46$) also fits quite well, this is discussed below. In terms of the structure function exponent, we have the relation $\beta = 1 + \xi(2)$ which follows from the Wiener–Khintchine theorem (the spectrum is the Fourier transform of the autocorrelation function, which is a second order statistic, hence the $q = 2$). On the other hand, the DFA-1 exponent was 1.09 ($\pm 0.04$), while by applying the DFA-$n$ with $n > 1$ on the detrended SIF data, the derived exponents ranged from 0.98 to 1.01.

Next, to summarize our results we analyzed the detrended SIF-WL data set by using Haar analysis (Lovejoy and Schertzer, 2012a, b) using the software available at http://www.physics.mcgill.ca/~gang/software/doc/haarpack.zip. According to Haar analysis, as also mentioned in Sect. 2, the variation of the SIF fluctuations vs. wavelength $\tau$ can be defined using the generalized $q$th order structure function $S_q(\tau) = \langle \Delta \text{SIF}(\tau)^q \rangle$, for which it holds that in a scaling regime $S_q(\tau) \approx \tau^{\delta q}$, where the exponent $\delta q(q > 0)$ is $H - K(q)$ and $K(q)$ illustrates the scaling intermittency (satisfying $K(1) = 0$ and $\xi(1) = H$). Figure 3b shows that $H=0.37$ and that the intermittency of SIF data set is very high ($C_1 = 0.16$, also, $\alpha \approx 1.7$), hence the RMS exponent $\delta = \xi(2)/2 = 0.23$ is quite different from the $q = 1$ exponent ($H$) and the data are far from Gaussian. In the classical quasi-Gaussian case, $K(q) = 0$ so that $\xi(q)$ is linear. More generally, if the field is intermittent – for example if it is the result of a multifractal process – then the exponent $K(q)$ is generally non-linear and convex and characterizes the intermittency, as already mentioned. The physical significance of $H$ is thus that it determines the rate at which mean fluctuations grow ($H > 0$) or decrease ($H < 0$) with scale $\tau$. According to Fig. 3a and b, the exponent $\xi(2)$ of the structure function equals to zero (at scales below 20 nm), a fact which means that the power spectrum exponent $\beta = 1 + \xi(2)$ equals to 1 ($1/f$ structure). On the other hand, at larger scales, the exponents $\xi(2)$ and $\beta$ seem to equal to 0.46 and 1.46, respectively.

To clarify this aspect, we revisited the results of DFA-1 (see Fig. 4a) and calculated the power spectrum for the detrended SIF-WL data set, using the MEM (see Fig. 4b). In Fig. 4a, we plot the root mean square fluctuation function $F_d(\tau)$ of DFA-1 together with the corresponding least-squares fits for $\tau$ up to 15 nm (blue) – leading to $a = 0.91$ ($\pm 0.08$) – and above 20 nm (green) with $a = 1.20$ ($\pm 0.09$). We observe a crossover approximately at $\tau = 23$ nm, leading to $\beta$ values (cf., $\beta = 2a - 1$, Talkner and Weber, 2000) above and below this crossover scale which are comparable to those found in the previous paragraph. In order to complement this finding, we plotted in Fig. 4b the MEM power spectral density vs. WL together with the aforementioned algebraic behaviors for WL above and below 20 nm. Interestingly, the results show that the $\beta = 1.46$ exponent better describes the
long WL body of the spectrum while the $\beta = 1$ the short WL part of it.

We observe that the DFA method gives results similar to those of the Haar analysis, but obscures the break that is clearly seen in the Haar analysis (Fig. 3). Finally, we have to recall that the $1/f$ scaling dynamics observed in SIF concerns not Planck’s law but the fluctuations about the law.

4 Conclusions

The main conclusions of the present survey were:

1. DFA-$n$ applied on the detrended SIF data set revealed DFA-exponents close to unity. In other words, the SIF fluctuations around the Planck’s law obey the $1/f$ scaling dynamics.

2. Power spectral density for the detrended SIF data set showed that the power-law fitting gives $\beta = 0.99$ ($\pm 0.08$) while DFA-1 exponent was $\alpha = 1.09$ ($\pm 0.04$) and DFA-$n$ exponents ranged from 0.98 to 1.01.

3. To better understand our results we analyzed the detrended SIF-WL data set by using Haar analysis. As it was derived, the intermittency of SIF data set was very high and the data were far from Gaussian. Specifically, the parameter characterizing the intermittency near the mean $C_1$ was $\approx 0.16$ and $\alpha \approx 1.7$. In comparison, in atmospheric turbulence, the wind field has $C_1 \approx 0.07$ (also with $\alpha \approx 1.7$). At scales below 20 nm, the power spectrum exponent $\beta$ was almost 1 ($1/f$ structure), while at larger scales, the exponents $\xi(2)$ and $\beta$ are equal to 0.46 and 1.46, respectively. This prompted us to revisit DFA-1 and search for such a crossover. Indeed a crossover at 20 nm can be observed leading to compatible $\beta$ exponents. The DFA method analyzed the running sum rather than the process directly; this made the scale break (crossover) very difficult to discern.

4. The results of the power spectral density for the detrended SIF-WL data set (using the MEM) vs. frequency are compatible with the aforementioned two $\beta$ exponents.
