Abstract. Many field experiments have found high nitrous acid (HONO) mixing ratios in both urban and rural areas during daytime, but these high daytime HONO mixing ratios cannot be explained well by gas-phase production, HONO emissions, and nighttime hydrolysis conversion of nitrogen dioxide (NO2) on aerosols, suggesting that an unknown daytime HONO source (Punknown) could exist. The formula Punknown ≈ 19.60[NO2] · J(NO2) was obtained using observed data from 13 field experiments across the globe. The three additional HONO sources (i.e., the Punknown, nighttime hydrolysis conversion of NO2 on aerosols, and HONO emissions) were coupled into the WRF-Chem model (Weather Research and Forecasting model coupled with Chemistry) to assess the Punknown impacts on the concentrations and budgets of HONO and peroxy (hydroxyl, hydroperoxyl, and organic peroxy) radicals (ROx) (= OH + HO2 + RO2) in the coastal regions of China. Results indicated that the additional HONO sources produced a significant improvement in HONO and OH simulations, particularly in the daytime. High daytime average Punknown values were found in the coastal regions of China, with a maximum of 2.5 ppb h−1 in the Beijing–Tianjin–Hebei region. The Punknown produced a 60–250 % increase of OH, HO2, and RO2 near the ground in the major cities of the coastal regions of China, and a 5–48 % increase of OH, HO2, and RO2 in the daytime meridional-mean mixing ratios within 1000 m above the ground. When the three additional HONO sources were included, the photolysis of HONO was the second most important source in the OH production rate in Beijing, Shanghai, and Guangzhou before 10:00 LST with a maximum of 3.72 ppb h−1 and a corresponding Punknown contribution of 3.06 ppb h−1 in Beijing, whereas the reaction of HO2 + NO (nitric oxide) was dominant after 10:00 LST with a maximum of 9.38 ppb h−1 and a corresponding Punknown contribution of 7.23 ppb h−1 in Beijing. The whole ROx cycle was accelerated by the three additional HONO sources, especially the Punknown. The daytime average OH production rate was enhanced by 0.67 due to the three additional HONO sources; [0.64], due to the Punknown, to 4.32 [3.86] ppb h−1, via the reaction of HO2 + NO, and by 0.49 [0.47] to 1.86 [1.86] ppb h−1, via the photolysis of HONO. The OH daytime average loss rate was enhanced by 0.58 [0.55] to 2.03 [1.92] ppb h−1, via the reaction of OH + NO2, and by 0.31 [0.28] to 1.78 [1.64] ppb h−1, via the reaction of OH + CO (carbon monoxide) in Beijing, Shanghai, and Guangzhou. Similarly, the three additional HONO sources produced an increase of 0.31 [0.28] (with a corresponding Punknown contribution) to 1.78 [1.64] ppb h−1, via the reaction of OH + CO, and 0.10 [0.09] to 0.63 [0.59] ppb h−1, via the reaction of CH3O2 (methylperoxy radical) + NO in the daytime average HO2 production rate, and 0.67 [0.61] to 4.32 [4.27] ppb h−1, via the reaction of HO2 + NO in the daytime average HO2 loss rate in Beijing, Shanghai, and Guangzhou. The above results suggest that the Punknown considerably enhanced the ROx concentrations and accelerated ROx cycles in the coastal regions of China, and could produce significant increases in concentrations of in-
organic aerosols and secondary organic aerosols and further aggravate haze events in these regions.

1 Introduction

The hydroxyl radical (OH) is the most dominant oxidant in the troposphere, initiating daytime photochemistry, removing the majority of reactive gases, and leading to the formation of secondary products (e.g., ozone (O₃), PANs (peroxycetyl nitrates), and aerosol) that can affect air quality, climate, and human health (Stone et al., 2012). OH is formed primarily through the photolysis of O₃, nitrous acid (HONO), hydrogen peroxide (H₂O₂), the reactions of O₃ with alkenes, and the hydroperoxyl radical (HO₂) to OH conversion process (HO₂ + NO) (Platt et al., 1980; Crutzen and Zimmermann, 1991; Atkinson and Aschmann, 1993; Fried et al., 1997; Paulson et al., 1997). Recent field experiments have found that the contribution of the photolysis of HONO to daytime OH production can reach up to 56, 42, and 33% in urban, rural and forest areas, respectively (Ren et al., 2003; Kleffmann et al., 2005; Acker et al., 2006), more than that of the photolysis of O₃. However, most current air quality models fail to predict observed HONO concentrations, underestimating daytime HONO in particular (Czader et al., 2012; Gonçalves et al., 2012; Li et al., 2011), due to the incomplete knowledge of HONO sources.

It is generally accepted that the photolysis of HONO (Reaction R2) in the early morning could be a major source of OH. After sunrise, HONO mixing ratios are usually in low concentrations due to the strong photolysis of HONO. However, many field experiments have found daytime HONO mixing ratios that are unexpectedly higher than the theoretical steady value (∼10 ppt), in both urban and rural areas: e.g., 0.15–1.50 ppb in Asia (Su et al., 2008; Wu et al., 2013; Spataro et al., 2013), 0.01–0.43 ppb in Europe (Kleffmann et al., 2005; Acker and Möller, 2007; Sörgel et al., 2011; Michoud et al., 2014), 0.02–0.81 ppb in North America (Zhou et al., 2002a, b; Ren et al., 2010; Villena et al., 2011; N. Zhang et al., 2012; Wong et al., 2012; VandenBoer et al., 2013), 2.00 ppb (maximum) in South America (Elshorbany et al., 2009), and 0.015–0.02 ppb in Antarctica (Kerbrat et al., 2012) (Fig. 1). These high HONO mixing ratios, particularly in the daytime, cannot be explained well by gas-phase production (Reaction R1), HONO emissions, and nighttime hydrolysis conversion of NO₂ on aerosols, suggesting that an unknown daytime HONO source (Punknown) could exist.

\[
\begin{align*}
\text{OH} + \text{NO} & \rightarrow \text{HONO} \quad \text{(R1)} \\
\text{HONO} + h\nu & \rightarrow \text{OH} + \text{NO} \quad \text{(R2)} \\
\text{HONO} + \text{OH} & \rightarrow \text{NO}_2 + \text{H}_2\text{O} \quad \text{(R3)}
\end{align*}
\]

The Punknown was calculated by Su et al. (2008) at Xinken (Guangzhou, China), with a maximum of 4.90 ppb h⁻¹. Spataro et al. (2013) proposed a Punknown value of 2.58 ppb h⁻¹ in Beijing. In fact, Punknown values, ranging from 0.06 to 4.90 ppb h⁻¹, have been obtained from many field studies across the globe, as shown in Fig. 1, suggesting Punknown could contribute greatly to the daytime production of OH and HO₂.

The most important formation pathway for nocturnal HONO could be the hydrolysis reaction of nitrogen dioxide (NO₂) on humid surfaces (Reaction R4) (Kleffmann et al., 1999; Alicke et al., 2002; Finlayson-Pitts et al., 2003):

\[
2\text{NO}_2 + \text{H}_2\text{O} \rightarrow \text{HONO} + \text{HNO}_3. \quad \text{(R4)}
\]

Ammann et al. (1998) found HONO formation via the heterogeneous reduction of NO₂ on the surface of soot (Reaction R5), and Reaction (R5) can be enhanced by irradiation (Monge et al., 2010):

\[
\text{NO}_2 + \text{red}_{\text{ads}} \rightarrow \text{HONO} + \text{ox}_{\text{ads}}. \quad \text{(R5)}
\]

George et al. (2005) and Stemmler et al. (2006, 2007) showed the heterogeneous reduction of NO₂ on organic surfaces (Reaction R6) (e.g., humic acid) to produce HONO:

\[
\text{NO}_2 + \text{HC}_{\text{red}} \rightarrow \text{HONO} + \text{HC}_{\text{ox}}. \quad \text{(R6)}
\]

Li et al. (2008) proposed a homogeneous reaction of photolytically excited NO₂ with H₂O (Reaction R7), but this reaction has been proven to be unimportant in the real atmosphere (Carr et al., 2009; Wong et al., 2011; Amedro et al., 2011). Zhang and Tao (2010) suggested the homogeneous nucleation of NO₂, H₂O, and ammonia (NH₃) for the production of HONO (Reaction R8), but Reaction (R8) has not yet been tested in laboratory studies, nor observed in field experiments:

\[
\text{NO}_2 + h\nu(\lambda > 420 \text{ nm}) \rightarrow \text{NO}_2^*. \quad \text{(R7)}
\]

\[
\text{NO}_2^* + \text{H}_2\text{O} \rightarrow \text{HONO} + \text{OH} \quad \text{(R7)}
\]

\[
\text{NO}_2^* + M \rightarrow \text{NO}_2 + M \quad \text{(R7)}
\]

\[
2\text{NO}_2 + \text{H}_2\text{O}(g) + \text{NH}_3 \rightarrow \text{HONO} + \text{NH}_4\text{NO}_3(s). \quad \text{(R8)}
\]

Zhou et al. (2002b, 2003, 2011) demonstrated that the photolysis of adsorbed nitric acid (HNO₃) and nitrate (NO₃⁻) at ultraviolet wavelengths (∼300 nm) (Reaction R9) can produce HONO:

\[
\text{HNO}_3/\text{NO}_3^- + h\nu \rightarrow \text{HONO}/\text{NO}_2^- + \text{O}. \quad \text{(R9)}
\]

Additionally, HONO could be emitted from soils (Su et al., 2011; Oswald et al., 2013), and may be important in farmland and forest areas.

Based on these mechanisms outlined above, some modeling studies have been carried out to simulate HONO concentrations (e.g., An et al., 2011; Czader et al., 2012; Gonçalves et al., 2012). Sarwar et al. (2008) incorporated Reactions (R4), (R9), and HONO emissions into the Community Multiscale Air Quality (CMAQ) model, but still underestimated HONO mixing ratios during daytime. Li et
al. (2010) considered both aerosol and ground surface reactions, and HONO emissions, in the WRF-Chem model (Weather Research and Forecasting model coupled with Chemistry), and found that HONO simulations were significantly improved. However, Li et al. (2010) used a relatively high emissions ratio of 2.3 \% for HONO/NO$_2$ to compute the direct emissions of HONO, which could have overestimated the HONO concentrations in the air (An et al., 2013). Czader et al. (2012) added Reactions (R6), (R7), and HONO emissions into the CMAQ model. The HONO simulations matched well with observations at night, but were significantly lower than observations at noon. Wong et al. (2013) reported good agreement between simulated and observed daytime HONO when HONO emissions, photolytically enhanced daytime formation mechanisms on both aerosols and the ground, and Reaction (R7), were included. However, according to our recent studies (Tang et al., 2014), this result depended heavily on the selection of uptake coefficients of NO$_2$ heterogeneous chemistry. Overall, the topic of HONO sources remains under discussion today, and so it is a challenge for modelers to decide which mechanism(s) to be coupled into an air quality model.

To investigate the importance of the mechanisms described above, correlation tests between the $P_{\text{unknown}}$ and NO$_2$, HNO$_3$, irradiation or the photolysis frequency of NO$_2$ [$J(\text{NO}_2)$], were conducted in field experiments (Acker and Möller, 2007; Sörgel et al., 2011; Villena et al., 2011; Wong et al., 2012). Many of these studies demonstrated that there is a clear dependency of the $P_{\text{unknown}}$ on irradiation /$J(\text{NO}_2)$ during daytime, particularly at noon. Rohrer et al. (2005) proposed that the photolytic HONO source at the surface of the chamber strongly depended on light intensity. Acker and Möller (2007) summarized field experiments in several European countries and showed a strong correlation ($R^2 = 0.81$) between the $P_{\text{unknown}}$ and $J(\text{NO}_2)$. Wong et al. (2012) also indicated that the $P_{\text{unknown}}$ showed a clear symmetrical diurnal variation with a maximum around noontime, closely correlated with actinic flux (NO$_2$ photolysis frequency) and solar irradiance; the correlation coefficient was over 0.70.

Besides irradiation /$J(\text{NO}_2)$, good correlations between the $P_{\text{unknown}}$ and NO$_2$ mixing ratios have been found from both field and laboratory studies, supporting the viewpoint that NO$_2$ is the primary precursor of HONO. Through estimating the $P_{\text{unknown}}$, Acker and Möller (2007) speculated that the daytime HONO levels might be explained by a fast electron transfer onto adsorbed NO$_2$. Sörgel et al. (2011) indicated that the conversion of NO$_2$ most likely accounted for light-induced HONO formation, about an order of magnitude stronger than HONO formation during nighttime. High correlations between the $P_{\text{unknown}}$ and NO$_2$ mixing ratios have also been found (e.g., $R^2 = 0.77$ in Qin et al., 2006, $R^2 = 0.80$ in Villena et al., 2011, and $R^2 = 0.62$ in Elshorbany et al., 2009), indicating that the photosensitized conversion of NO$_2$ is more likely to be the daytime HONO source. This is the reason why the recent CalNex 2010 (California Research at the Nexus of Air Quality and Climate Change) study found a very strong positive correlation ($R^2 = 0.985$) between HONO flux and the product of NO$_2$ concentration and solar radiation at the Bakersfield site (Ren et al., 2011).

Based on the studies introduced above, the $P_{\text{unknown}}$ calculated from field experiments may be a practical method to help quantify the daytime HONO source. In this study, field
experiment data from 13 different field campaigns across the globe were used to express the \( P_{\text{unknown}} \) as a function of \( \text{NO}_2 \) mixing ratios and \( J(\text{NO}_2) \) (see Sect. 2.2). We then added the \( P_{\text{unknown}} \) into the WRF-Chem model to assess the impacts of the \( P_{\text{unknown}} \) on the concentrations and production and loss rates of HONO, OH, HO\(_2\), and organic peroxy radicals (RO\(_2\)).

2 Data and methods

2.1 Observed data

Anthropogenic emissions were based on the year 2006/2007. Limited measurements of HONO, OH, and HO\(_2\) in the coastal regions of China were made in the summers of 2006/2007, so these limited measurements were used for model evaluation. Observed air temperature (TA), relative humidity (RH), wind speed (WS), and direction (WD) near the ground were obtained from the National Climatic Data Center, China Meteorological Administration (H. Zhang et al., 2012). Surface mixing ratios of O\(_3\) and \( \text{NO}_2 \) in Beijing were obtained from the Beijing Atmospheric Environmental Monitoring Action, carried out by the Chinese Academy of Sciences (Li et al., 2011; Wang et al., 2014), except those in Guangzhou, which were sourced from Qin et al. (2009). HONO observations were conducted using two annular denuders at the campus of Peking University (39°59’N, 116°18’E) in Beijing on 17–20 August 2007 (Spataro et al., 2013) and a long path absorption photometer at the Backgarden (BG) supersite (23°30’N, 113°10’E), about 60 km northwest of Guangzhou on 3–31 July 2006 (X. Li et al., 2012). The measurement systems are described in detail in Spataro et al. (2013) and X. Li et al. (2012). OH and HO\(_2\) were measured by laser-induced fluorescence at the BG supersite on 3–30 July 2006 (Lu et al., 2012).

2.2 Parameterization of HONO sources

Besides HONO gas-phase production from Reaction (R1), three additional HONO sources [HONO emissions, Reaction (R4) (nighttime), and the \( P_{\text{unknown}} \)] were coupled into the WRF-Chem model in this work.

HONO emissions were calculated using \[ 0.023 \times f_{DV} + 0.008 \times (1 - f_{DV}) \times f_{TS}, \] where \( f_{DV} \) denotes the nitrogen oxides (NO\(_x\)) emissions ratio of diesel vehicles to total vehicles, and \( f_{TS} \) is the NO\(_x\) emissions ratio of the traffic source to all anthropogenic sources (Li et al., 2011; An et al., 2013; Tang et al., 2014). Reaction (R4) was inserted into the Carbon-Bond Mechanism Z (CBM-Z) during nighttime only. The heterogeneous reaction rate was parameterized by \[ k = \left( \frac{a}{D_g} + \frac{4}{v_f} \right)^{-1} A_s \] (Jacob, 2000), where \( a \) is the radius of aerosols, \( v \) is the mean molecular speed of \( \text{NO}_2 \), \( D_g \) is a gas-phase molecular diffusion coefficient taken as \( 10^{-5} \text{ m}^2 \text{ s}^{-1} \) (Dentener and Crutzen, 1993), and \( A_s \) is the aerosol surface area per unit volume of air, calculated from aerosol mass concentrations and number density in each bin set by the Model for Simulating Aerosol Interactions and Chemistry (MOSAIC). Hygroscopic growth of aerosols was considered (Li et al., 2011).

Previous studies (Sörgel et al., 2010; Villena et al., 2011; Wong et al., 2012) have shown \( P_{\text{unknown}} \propto [\text{NO}_2] \cdot J(\text{NO}_2) \). To quantify the relationship between the \( P_{\text{unknown}} \) and \( \text{NO}_2 \)
mixing ratios and irradiation, daytime $P_{\text{unknown}}$, NO$_2$ mixing ratios and $J(\text{NO}_2)$, based on all the available data sets from 13 different field campaigns across the globe (Table S1 in the Supplement), were plotted in Fig. 2. As expected, good correlation ($R^2 = 0.75$) between the $P_{\text{unknown}}$ and NO$_2$ mixing ratios was obtained (Fig. 2a). Furthermore, the correlation ($R^2$) between the $P_{\text{unknown}}$ and $[\text{NO}_2] \cdot J(\text{NO}_2)$ was increased to 0.80, with a linear regression slope of 19.60 (Fig. 2b). For the coastal regions of China (mainly including Liaoning, Beijing, Tianjin, Hebei, Shandong, Jiangsu, Anhui, Shanghai, Zhejiang, Jiangxi, Fujian, and Guangdong), the correlation between the $P_{\text{unknown}}$ and $[\text{NO}_2] \cdot J(\text{NO}_2)$ was 0.48, with a linear regression slope of 17.37 (Fig. S2b in the Supplement), which is within the maximum $P_{\text{unknown}}$ uncertainty range of 25% (Table S1). The $P_{\text{unknown}}$ could be expressed as a function of NO$_2$ mixing ratios and $J(\text{NO}_2)$, i.e., $P_{\text{unknown}} \approx 19.60[\text{NO}_2] \cdot J(\text{NO}_2)$. This formula is very similar to $P_{\text{unknown}} \approx \alpha \cdot J(\text{NO}_2) \cdot [\text{NO}_2] \cdot [\text{H}_2\text{O}] \cdot (S/V_a + S/V_{\text{a}})$ proposed by Su et al. (2008), and $P_{\text{unknown}} \approx 3.3 \times 10^{-3}[\text{NO}_2] \cdot Q_s$ suggested by Wong et al. (2012) as an additional daytime source of HONO through analysis of observed data, where $S/V_a$ is the aerosol surface area-to-volume ratio, $S/V_{\text{a}}$ is the ground surface area-to-volume ratio, $\alpha$ is a fitting parameter, and $Q_s$ is solar visible irradiance. Recently, Li et al. (2014) suggested that high HONO mixing ratios in the residual layer in the studied Po Valley in Italy were mainly from a gas-phase source (SHONO) that consumed NO$_x$ (Li et al., 2015), and $S_{\text{HONO}}$ was proportional to the photolysis frequency of HONO $[J(\text{HONO})]$, basically consistent with our result that the $P_{\text{unknown}}$ was proportional to NO$_2$ mixing ratios and the photolysis frequency of NO$_2$ $[J(\text{NO}_2)]$.

2.3 Model setup

The WRF-Chem model version 3.2.1 (Grell et al., 2005; Fast et al., 2006), with the CBM-Z (Zaveri and Peters, 1999) and the MOSAIC (Zaveri et al., 2008), was used in this study. The detailed physical and chemical schemes for the simulations can be found in Tang et al. (2014). Two domains with a horizontal resolution of 27 km were employed in this study: domain 1 covered East Asia, whereas domain 2 covered the coastal regions of China, including the Beijing–Tianjin–Hebei region (BTH), the Yangtze River delta (YRD), and the Pearl River delta (PRD) (Fig. 3), which are the three most rapidly developing economic growth regions of China. Rapid economic development and urbanization has led to a serious deterioration in air quality in these three regions. Beijing, Shanghai, and Guangzhou are three representative cities of the three regions, so this study focuses on the three regions, including the three representative cities. There were 28 vertical model layers from the ground to 50 hPa, and the first model layer was $\sim 28$ m above the ground. Meteorological initial and boundary conditions were obtained from the NCEP (National Centers for Environmental Prediction) $1^\circ \times 1^\circ$ reanalysis data set. Chemical initial and boundary conditions were constrained with the output of MOZART-4 (Model for Ozone and Related chemical Tracers, version 4) (Emmons et al., 2010), every 6 h. Monthly anthropogenic emissions in 2006/2007 and biogenic emissions were the same as those used by Li et al. (2011) and An et al. (2013).

Six simulations (cases R, $\text{R}_{\text{wop}}$, and $\text{R}_{p}$, performed for the entire months of August 2007 and July 2006), with a spin-up period of 7 days, were conducted to assess the $P_{\text{unknown}}$ effects on the concentrations and budgets of HONO, OH, HO$_2$, and RO$_2$. Case R only considered Reaction (R1) as a reference; Case $\text{R}_{\text{wop}}$ included case R with HONO emissions, and Reaction (R4) only at night; case $\text{R}_{p}$ contained case $\text{R}_{\text{wop}}$ with the $P_{\text{unknown}}$ $[\approx 19.60[\text{NO}_2] \cdot J(\text{NO}_2)]$. The $P_{\text{unknown}}$ and Reaction (R4) were added to the CBM-Z, and diagnostic variables (i.e., production and loss rates of HONO, OH, HO$_2$, RO$_2$, O$_3$, and other species) were inserted into the CBM-Z to quantify the $P_{\text{unknown}}$ impacts on the budgets of HONO, OH, HO$_2$, and RO$_2$ (Wang et al., 2014).

3 Results and discussion

3.1 Comparison of simulations and observations

The statistical metrics of mean bias (MB), mean error (ME), root-mean-square error (RMSE), normalized mean bias (NMB), normalized mean error (NME), index of agreement (IOA), and correlation coefficient (CC), were used. The MB, ME, and RMSE are given in the same units as the measurements (absolute metrics). The MB quantifies the tendency of the model to over- or underestimate values, while the ME and RMSE measure the magnitude of the difference between modeled and observed values, regardless of whether the modeled values are higher or lower than observations. One disadvantage of absolute metrics is that they make intercomparisons of model performance in clean and polluted environments or across different pollutants difficult to interpret. Consequently, a range of relative metrics are often used. These metrics are presented either in fractional or percentage units. The NMB and NME all normalize by observed values. The IOA and CC provide a sense of the strength of the relationship between model estimates and observations that have been paired in time and space. Perfect agreement for any metric alone may not be indicative of good model performance, so multiple metrics must be considered when evaluating model performance. Simulations of TA, RH, WS and WD were compared with observations, as shown in Wang et al. (2014). The MB, ME, RMSE, NMB, NME, IOA, and CC were comparable with those of Wang et al. (2010) and L. Li et al. (2012) using MM5 (the fifth-generation Pennsylvania State University/National Center for Atmospheric Research Mesoscale Model), and H. Zhang et al. (2012) using the WRF model. For O$_3$ in Beijing of the BTH region and Guangzhou of the PRD region, the NMB, NME, and IOA were $-22.80$, 58.70, and 0.79%, respectively (Table 1

www.atmos-chem-phys.net/15/9381/2015/
for case R), comparable to the values of 30.2 % for NMB, 55.8 % for NME, and 0.91 for IOA, reported in L. Li et al. (2012) using the CMAQ model. When HONO emissions, Reaction (R4), and the \( P_{\text{unknown}} \) were included, the NMB, NME, and IOA increased to \(-2.20\), 66.10 %, and 0.80, respectively (Table 1 for case \( R_p \)). The \( \text{NO}_2 \) fluctuations were generally captured (Fig. 4) but the simulated amplitude of \( \text{NO}_2 \) was underestimated in some cases (Fig. 4). This underestimation could be related to the uncertainty of \( \text{NO}_x \) emissions. For \( \text{NO}_2 \) in case R, the NMB, NME, and IOA were \(-13.50\), 42.10 %, and 0.57, respectively (Table 1), similar to the results of Wang et al. (2010) using the CMAQ model (NMB of \(-33.0\) %, NME of 50.0 %, and IOA of 0.61). Compared with case R, \( \text{NO}_2 \) simulations (Table 1 for case \( R_p \)) were further underestimated for case \( R_p \) due to the underestimation of \( \text{NO}_x \) emissions in Guangzhou.

HONO simulations only with the gas-phase production (case R) were always substantially underestimated compared with observations (Fig. 5), similar to the results of Sarwar et al. (2008), Li et al. (2011), and An et al. (2013). When HONO emissions and Reaction (R4) were included, HONO simulations were significantly improved, especially at night (Fig. 5 and Table 2 for case \( \text{R}_{\text{wop}} \)). For Beijing, the nighttime RMSE and NME were reduced by \( 0.90 \times 10^6 \) molecules cm\(^{-3} \) and 44.70 %, whereas the NMB and IOA were increased by 50.00 % and 0.29, respectively (Table 2). For Guangzhou, the nighttime RMSE and NME were reduced by \( 0.44 \times 10^6 \) molecules cm\(^{-3} \) and 32.90 %, and the NMB and IOA were enhanced by 58.80 % and 0.18, respectively. When the \( P_{\text{unknown}} \) was included, daytime HONO simulations were considerably improved (Fig. 5 and Table 2 for case \( R_p \)). Compared with case \( \text{R}_{\text{wop}} \), the daytime NME in Beijing was reduced by 19.60 %, and the NMB and IOA in Beijing were increased to \(-24.30\) from \(-62.00\) % and 0.73 from 0.64, respectively (Table 2); the daytime NME in Guangzhou was reduced by 8.10 %, and the NMB in Guangzhou was increased to \(-61.20\) from \(-76.50\) % (Table 2).

Simulated diurnal variations of \( \text{OH} \) and \( \text{HO}_2 \) showed consistent patterns with the observed data (Fig. 6). When HONO emissions and Reaction (R4) were considered (case \( \text{R}_{\text{wop}} \)), \( \text{OH} \) and \( \text{HO}_2 \) enhancements were \( \leq \sim 6\) % in most cases compared with case R (Fig. 6 and Table 3), but the \( P_{\text{unknown}} \) led to 10–150 % improvements in \( \text{OH} \) simulations on 5–12 July 2006 (Fig. 6). The 20–90 % overestimation of \( \text{OH} \) mixing ratios on 20–25 July 2006 (Fig. 6) needs further investigation. Compared with case R, the NME was reduced by 79.60 % (i.e., \( 136.60 - 57.00\) %), whereas the NMB was increased by 105.40 % (123.00 – \( 17.60\) %), and the IOA was improved to 0.84 from 0.79 (Table 3). When the \( P_{\text{unknown}} \) was considered, \( \text{HO}_2 \) simulations were substantially improved (Fig. 6), the IOA was improved to 0.61 from 0.54, and the CC was improved to 0.66 from 0.57 (Table 3). However, \( \text{HO}_2 \) simulations were still substantially underestimated (Fig. 6).

Figure 5. Comparison of simulated and observed hourly mean HONO mixing ratios at the Peking University site in (a) Beijing on 17–20 August 2007 (Spataro et al., 2013) and (b) the Backgarden site in Guangzhou on 11–25 July 2006 (X. Li et al., 2012).

One of the major reasons for the HO$_2$ underestimation could be related to the considerable underestimation of anthropogenic volatile organic compounds (VOCs) (Wang et al., 2014).

3.2 $P_{\text{unknown}}$ simulations and its impacts on production and loss rates of HONO

High $P_{\text{unknown}}$ values were found in the coastal regions of China (Fig. 7), especially in the BTH, YRD, and PRD regions due to elevated emissions of NO$_x$ (Zhang et al., 2009). The largest daytime average $P_{\text{unknown}}$ value reached 2.5 ppb h$^{-1}$ in Tianjin of the BTH region (Fig. 7a), whereas it was 2.0 ppb h$^{-1}$ in Shanghai of the YRD region (Fig. 7b). The largest daytime average $P_{\text{unknown}}$ value reached 1.2 ppb h$^{-1}$ in Guangzhou and Shenzhen of the PRD (Fig. 7c), lower than the values of 2.5 ppb h$^{-1}$ and 2.0 ppb h$^{-1}$. One major reason is the underestimation of daytime NO$_2$ mixing ratios in the PRD (Fig. 4b).

For case R, daytime HONO production was primarily from the reaction of OH and nitric oxide (NO) (Reaction R1), with a maximum production rate of 0.69 ppb h$^{-1}$ in Beijing, 1.20 ppb h$^{-1}$ in Shanghai, and 0.72 ppb h$^{-1}$ in Guangzhou near noon due to high OH mixing ratios (Fig. 8a, c, e). The loss rate of HONO was 0.62 ppb h$^{-1}$ in Beijing, 1.09 ppb h$^{-1}$ in Shanghai, and 0.65 ppb h$^{-1}$ in Guangzhou via Reaction (R2), much higher than the 0.01–0.02 ppb h$^{-1}$ in Beijing, Shanghai, and Guangzhou via Reaction (R3) (Fig. 8b, d, f), indicating that Reaction (R2) accounted for approximately 99% of the total loss rate of HONO.

When the additional HONO sources (HONO emissions, Reaction (R4), and the $P_{\text{unknown}}$) were coupled into the WRF-Chem model, nighttime HONO was formed mainly via Reaction (R4) (0.30–1.42 ppb h$^{-1}$ in Beijing, 0.20–0.45 ppb h$^{-1}$ in Shanghai, and 0.25–0.84 ppb h$^{-1}$ in Guangzhou) (Fig. 8a, c, e). HONO emissions contributed 0.04–0.62 ppb h$^{-1}$ to HONO production (Fig. 8a, c, e). Simulated $P_{\text{unknown}}$ values ranged from 0.42 to 2.98 ppb h$^{-1}$ in Beijing, from 0.18 to 2.58 ppb h$^{-1}$ in Shanghai, and from
0.06 to 1.66 ppb h\(^{-1}\) in Guangzhou (Fig. 8a, c, e). The simulated \(P_{\text{unknown}}\) values in Beijing (Fig. 8a) were in good agreement with the results of Spataro et al. (2013), with an average unknown daytime HONO production rate of 2.58 ppb h\(^{-1}\) in the studied summer period. However, the simulated \(P_{\text{unknown}}\) values in Guangzhou (Fig. 8e) were lower than the 2.36–4.90 ppb h\(^{-1}\) reported by Su et al. (2008), due mainly to the underestimation of the daytime NO\(_2\) mixing ratios in the PRD region. The additional HONO sources produce more HONO, which subsequently photolyzes to yield more OH. Therefore, the formation of HONO through Reaction (R1) was greatly enhanced, with a maximum of 4.70 [1.44] (due to the \(P_{\text{unknown}}\)) ppb h\(^{-1}\) in Beijing, 4.25 [3.13] ppb h\(^{-1}\) in Shanghai, and 1.58 [0.40] ppb h\(^{-1}\) in Guangzhou in the morning (Fig. 8a, c, e), much higher than the 0.69 ppb h\(^{-1}\) in Beijing, 1.20 ppb h\(^{-1}\) in Shanghai, and 0.72 ppb h\(^{-1}\) in Guangzhou, respectively, for case R (Fig. 8a, c, e). Meanwhile, the loss rate of HONO via Reaction (R2) was significantly enhanced, with a maximum enhancement of 5.20 (i.e., 5.82 – 0.62) [1.97] (due to the \(P_{\text{unknown}}\)) ppb h\(^{-1}\) in Beijing, 4.31 (i.e., 5.40 – 1.09) [1.44] ppb h\(^{-1}\) in Shanghai, and 1.96 (i.e., 2.61 – 0.65) [1.18] ppb h\(^{-1}\) in Guangzhou (Fig. 8b, d, f). The HONO loss rate via dry deposition ranged from 0.28 to 0.45 ppb h\(^{-1}\) (not shown), roughly equivalent to the contribution of HONO emissions, suggesting that dry deposition of HONO cannot be neglected in high NO\(_x\) emission areas. The maximum \(P_{\text{unknown}}\) uncertainty range of 25 % (Table S1), a 25 % increase (decrease) in the slope factor (19.60) led to a 9.19–18.62 % increase (a 8.40–14.32 % decrease) in the maximum production and loss rate of HONO (Fig. S3 in the Supplement).

### 3.3 \(P_{\text{unknown}}\) impacts on concentrations of OH, HO\(_2\), and RO\(_2\)

Incorporation of the \(P_{\text{unknown}}\) into the WRF-Chem model led to substantial enhancements in the daytime average mixing ratios of OH in the coastal regions of China, e.g., 60–190 % in the BTH region, 60–210 % in the YRD region, and 60–200 % in the PRD region (Fig. 9a). The maximum enhancement of HO\(_2\) reached 250 % in the BTH region, 200 % in the YRD region, and 140 % in the PRD region (Fig. 9b). Similarly, a daytime average increase of 100–180, 60–150, and 40–80 % in RO\(_2\) (i.e., CH\(_3\)O\(_2\) (methylperoxy radical) +...
Figure 8. Production \( \mathcal{P}(\text{HONO}) \) and loss \( \mathcal{L}(\text{HONO}) \) rates of HONO for cases R (dashed lines) and \( \text{R}_p \) (solid lines) in (a, b) Beijing, (c, d) Shanghai, and (e, f) Guangzhou in August 2007.

Figure 9. Daytime (06:00–18:00 LST) percentage enhancements of (a) OH, (b) \( \text{HO}_2 \), and (c) \( \text{RO}_2 \) due to the unknown daytime HONO source (case \( \text{R}_p \) – case \( \text{R}_\text{wop} \)) in the coastal regions of China in August 2007.

ETHP (ethyl peroxy radical) + \( \text{C}_2\text{O}_3 \) (peroxyacyl radical + others) were found in the BTH, YRD, and PRD regions, respectively (Fig. 9c).

Vertically, the \( P_{\text{unknown}} \) enhanced the monthly meridional-mean daytime (06:00–18:00 LST) mixing ratios of OH, \( \text{HO}_2 \), and \( \text{RO}_2 \) by 5–38, 5–47, and 5–48 \%, respectively, within 1000 m above the ground in the coastal regions of China (Fig. 10). Strong vertical mixing in the daytime in summer led to a roughly uniform vertical enhancement of OH, \( \text{HO}_2 \), and \( \text{RO}_2 \) within 1000 m at the same latitude (Fig. 10). Different \( P_{\text{unknown}} \) values in different latitudes produced distinct differences in the enhancements of OH, \( \text{HO}_2 \), and \( \text{RO}_2 \), with a maximum located near 35\(^\circ\) N (Fig. 10).
3.4 $P_{\text{unknown}}$ impacts on the budgets of OH, HO$_2$, and RO$_2$

OH radicals are produced mainly through the reaction of HO$_2$ + NO, the photolysis of O$_3$ and HONO, and the reactions between O$_3$ and alkenes (Fig. 11). For case R, the predominant contribution to P(OH) (production rate of OH) was the reaction of HO$_2$ + NO (Fig. S1a, c, e), and the photolysis of O$_3$ was the second most important source of OH (Fig. S1a, c, e). When the three additional HONO sources were added, the most important source was the reaction of HO$_2$ + NO, with a diurnal maximum conversion rate reaching 9.38 [7.23] (due to the $P_{\text{unknown}}$) ppb h$^{-1}$ in Beijing, 2.63 [1.15] ppb h$^{-1}$ in Shanghai, and 4.88 [1.43] ppb h$^{-1}$ in Guangzhou near noon (Fig. 11a, c, e). The photolysis of HONO became the second most important source of OH in Beijing and Guangzhou before 10:00 LST, and in Shanghai before 12:00 LST; the diurnal peaks were 3.72 [3.06] ppb h$^{-1}$ in Beijing at 09:00 LST, 0.89 [0.62] ppb h$^{-1}$ in Shanghai at 11:00 LST, and 0.97 [0.78] ppb h$^{-1}$ in Guangzhou at 09:00 LST (Fig. 11a, c, e), which were comparable to or lower than the 3.10 ppb h$^{-1}$ reported by Elshorbany et al. (2009). Kanaya et al. (2009), who also conducted similar studies at Mount Tai (located in a rural area) of China, using an observationally constrained box model, suggested that the reaction of HO$_2$ + NO was the predominant OH source, with a daytime average of 3.72 ppb h$^{-1}$, more than the 1.38 ppb h$^{-1}$ of the photolysis of O$_3$. Using an observationally constrained box model, Hens et al. (2014) reported similar results in a boreal forest, in which the dominant contributor to OH was the reaction of HO$_2$ + NO, ranging from 0.23 to 1.02 ppb h$^{-1}$ during daytime. The production rates of OH in our study were higher than in Kanaya et al. (2009) and Hens et al. (2014) due to higher NO$_x$ emissions in urban areas than in rural areas.

Recently, Li et al. (2014) proposed an assumed HONO source through the reaction between NO$_2$ and the hydroperoxyl-water complex (HO$_2$.H$_2$O), and suggested that the impact of HONO on hydrogen oxide radicals (HO$_x$) budget could be overestimated because this source mechanism consumed HO$_x$ radicals. However, Ye et al. (2015) argued that the HONO yield for the reaction above is too small (with an upper-limit yield of 0.03) to explain the observation of HONO in the study of Li et al. (2014), and Li et al. (2015) agreed that the reaction of HO$_2$.H$_2$O + NO$_2$ is not a significant HONO source, suggesting that HONO remains an important net OH precursor, as demonstrated by many field studies (e.g., Kleffmann et al., 2005; Acker et al., 2006) and our simulations.

The dominant loss rate of OH was the reaction of OH + NO$_2$ for both cases R and Rp (Figs. 11b, d, f and S1b, d, f). The diurnal maximum loss rates were 1.98 ppb h$^{-1}$ in Beijing, 1.12 ppb h$^{-1}$ in Shanghai, and 1.70 ppb h$^{-1}$ in Guangzhou for case R (Fig. S1b, d, f), whereas these values were 5.61 [4.38] (due to the $P_{\text{unknown}}$) ppb h$^{-1}$ in Beijing, 2.00 [1.00] ppb h$^{-1}$ in Shanghai, and 2.65 [1.02] ppb h$^{-1}$ in Guangzhou for case Rp (Fig. 11b, d, f). The reactions of OH + VOCs to form HO$_2$ and RO$_2$ were the second most important loss path of OH, with a diurnal maximum of 0.75–1.73 ppb h$^{-1}$ for case R (Fig. S1b, d, f) and 1.57 [0.82] (due to the $P_{\text{unknown}}$) to 5.37 [4.05] ppb h$^{-1}$ for case Rp in Beijing, Shanghai, and Guangzhou (Fig. 11b, d, f). The third most important OH loss path was the reaction of OH + CO to form HO$_2$; the diurnal maximum rates were 0.46–1.47 ppb h$^{-1}$ for case R (Fig. S1b, d, f) and 0.93 [0.49] (due to the $P_{\text{unknown}}$) to 3.58 [2.86] ppb h$^{-1}$ for case Rp in Beijing, Shanghai and Guangzhou (Fig. 11b, d, f).

The averaged radical conversion rates in the daytime (06:00–18:00 LST) are illustrated in Fig. 12. OH radicals are produced mainly via the photolysis of O$_3$, HONO, and hydrogen peroxide (H$_2$O$_2$), and the reactions between O$_3$ and alkenes, after which OH radicals enter the RO$_2$ cycle (i.e., OH + HO$_2$.RO$_2$ cycle (Fig. 12 and Tables 4, S2, and S3). For case R, the reaction of HO$_2$ + NO was the major source of OH (2.78 ppb h$^{-1}$ (81.73 % of the total daytime average production rate of OH) in Beijing, 0.73 ppb h$^{-1}$ in Shanghai, and 1.70 ppb h$^{-1}$ in Guangzhou for case R). The dominant OH loss is the reaction of OH + NO$_2$ for both cases R and Rp (Fig. 11b, d, f). The diurnal maximum loss rates were 1.98 ppb h$^{-1}$ in Beijing, 1.12 ppb h$^{-1}$ in Shanghai, and 1.70 ppb h$^{-1}$ in Guangzhou for case R (Fig. S1b, d, f), whereas these values were 5.61 [4.38] (due to the $P_{\text{unknown}}$) ppb h$^{-1}$ in Beijing, 2.00 [1.00] ppb h$^{-1}$ in Shanghai, and 2.65 [1.02] ppb h$^{-1}$ in Guangzhou for case Rp (Fig. 11b, d, f). The reactions of OH + VOCs to form HO$_2$ and RO$_2$ were the second most important loss path of OH, with a diurnal maximum of 0.75–1.73 ppb h$^{-1}$ for case R (Fig. S1b, d, f) and 1.57 [0.82] (due to the $P_{\text{unknown}}$) to 5.37 [4.05] ppb h$^{-1}$ for case Rp in Beijing, Shanghai, and Guangzhou (Fig. 11b, d, f).

The averaged radical conversion rates in the daytime (06:00–18:00 LST) are illustrated in Fig. 12. OH radicals are produced mainly via the photolysis of O$_3$, HONO, and hydrogen peroxide (H$_2$O$_2$), and the reactions between O$_3$ and alkenes, after which OH radicals enter the RO$_2$ cycle (i.e., OH + HO$_2$.RO$_2$ cycle (Fig. 12 and Tables 4, S2, and S3).

For case R, the reaction of HO$_2$ + NO was the major source of OH (2.78 ppb h$^{-1}$ (81.73 % of the total daytime average production rate of OH) in Beijing, 0.73 ppb h$^{-1}$ in Shanghai, and 1.70 ppb h$^{-1}$ in Guangzhou).
(67.09 %) in Shanghai, and 1.75 ppb h⁻¹ (71.54 %) in Guangzhou) (Fig. 12a and Table 4). The second largest source of OH was the photolysis of O₃ (Table 4). OH radicals were removed mainly through the reaction of OH + NO₂ (1.12 ppb h⁻¹ (39.31 % of the total daytime average loss rate of OH) in Beijing, 0.47 ppb h⁻¹ (46.63 %) in Shanghai, and 0.77 ppb h⁻¹ (38.33 %) in Guangzhou) (Table 4), whereas those were converted to HO₂ mainly via the reaction of OH + CO (Table 4). For HO₂, the predominant production pathways were the reactions of OH + CO and CH₃O₂ + NO and the photolysis of formaldehyde (HCHO) (Table S2). HO₂ radicals were consumed primarily via the reaction of HO₂ + NO (2.78 ppb h⁻¹ (99.34 %) in Beijing, 0.73 ppb h⁻¹ (99.61 %) in Shanghai, and 1.75 ppb h⁻¹ (98.29 %) in Guangzhou) (Table S2). RO₂ radicals were formed mainly from the reactions of OH + OLET (terminal olefin carbons)/OLEI (internal olefin carbons), OH + ETH (ethene), OH + methane (CH₄), and OH + AONE (acetone). RO₂ radicals were consumed primarily via the reaction of CH₃O₂ + NO (0.54 ppb h⁻¹ (94.56 %) in Beijing, 0.16 ppb h⁻¹ (95.28 %) in Shanghai, and 0.33 ppb h⁻¹ (96.07 %) in Guangzhou) (Table S3).

When the three additional HONO sources were inserted into the WRF-Chem model (case R₀), the daytime average OH production rate was enhanced by 4.32 (i.e., 7.10 – 2.78) [3.86] (due to the Punknown) ppb h⁻¹ in Beijing, 0.67 (i.e., 1.40 – 0.73) [0.64] ppb h⁻¹ in Shanghai, and 0.80 (i.e., 2.55 – 1.75) [0.68] ppb h⁻¹ in Guangzhou via the reaction of HO₂ + NO, and by 1.86 [1.86] ppb h⁻¹ in Beijing, 0.50 [0.50] ppb h⁻¹ in Shanghai, and 0.49 [0.47] ppb h⁻¹ in Guangzhou via the photolysis of HONO, respectively (Table 4). The enhancements of the daytime average OH production due to the photolysis of HONO were comparable to or lower than the 2.20 ppb h⁻¹ obtained by Liu et al. (2012). The daytime average OH loss rate was increased by 2.03 [1.92] (due to the Punknown) ppb h⁻¹ in Beijing, 0.58 [0.55] ppb h⁻¹ in Shanghai, and 0.65 [0.58] ppb h⁻¹ in Guangzhou via the reaction of OH + NO₂, and by 1.78 [1.64] ppb h⁻¹ in Beijing, 0.31 [0.28] ppb h⁻¹ in Shanghai, and 0.42 [0.36] ppb h⁻¹ in Guangzhou via the reaction of OH + CO, respectively (Table 4). Similarly, the daytime average HO₂ production rate was increased by 0.31 [0.28] (due to the Punknown) to 1.78 [1.64] ppb h⁻¹ in Beijing, Shanghai and Guangzhou via the reaction of OH + CO, and by 0.63 [0.59] ppb h⁻¹ in Beijing, 0.10 [0.09] ppb h⁻¹ in Shanghai, and 0.19 [0.17] ppb h⁻¹ in Guangzhou via the reaction of CH₃O₂ + NO; whereas, the daytime average HO₂ loss rate was enhanced by 0.67 [0.61] (due to the Punknown) to 4.32 [4.27] ppb h⁻¹ in Beijing, Shanghai and Guangzhou via the reaction of HO₂ + NO (Table S2).

Overall, the net daytime production rate of RO₂ was increased to 3.48 (i.e., 2.56 + 0.71 + 0.21) [2.06] (due to the Punknown) from 1.20 (i.e., 0.60 + 0.43 + 0.17) ppb h⁻¹ in Beijing, 1.09 (i.e., 0.86 + 0.19 + 0.04) [0.45] from 0.54

**Figure 11.** Averaged production \[P(\text{OH})\] and loss \[L(\text{OH})\] rates of OH for case R₀ in (a, b) Beijing, (c, d) Shanghai, and (e, f) Guangzhou in August 2007. (HONO+hv)\text{net} means the net OH production rate from HONO photolysis (subtracting OH + NO results in HONO).
Figure 12. Daytime (06:00–18:00 LST) average budgets of OH, HO$_2$ and RO$_2$ radicals (reaction rates, ppb h$^{-1}$) for cases (a) R and (b) R$_p$ in Beijing/Shanghai/Guangzhou in August 2007.

(i.e., 0.36 + 0.14 + 0.04) ppb h$^{-1}$ in Shanghai, and 1.52 (i.e., 1.21 + 0.26 + 0.05) [0.58] from 0.92 (i.e., 0.68 + 0.20 + 0.04) ppb h$^{-1}$ in Guangzhou (Fig. 12) due to the three additional HONO sources, indicating that the RO$_x$ source was mainly from OH production, especially via the photolysis of HONO (Tables 4, S2 and S3). This result is different from the conclusion of Liu et al. (2012) that the photolysis of HONO and oxygenated VOCs is the largest RO$_x$ source. One of the primary reasons for this is the underestimation of anthropogenic VOCs (Wang et al., 2014). For Beijing, the net production rate of RO$_x$ was 3.48 ppb h$^{-1}$, lower than the 6.60 ppb h$^{-1}$ from the field studies of Liu et al. (2012). Our results reconfirmed the view of Ma et al. (2012) that the North China Plain acts as an oxidation pool. The additional HONO sources produced an increase of 2.03 [1.96] (due to the $P_{\text{unknown}}$) ppb h$^{-1}$ in Beijing, 0.56 [0.54] ppb h$^{-1}$ in Shanghai, and 0.66 [0.59] ppb h$^{-1}$ in Guangzhou in the net loss rate of RO$_x$ (Fig. 12).

4 Conclusions

The relationship between the $P_{\text{unknown}}$, NO$_2$ mixing ratios and J(NO$_2$) was investigated using available data from 13 field studies across the globe. The formula $P_{\text{unknown}} \approx 19.6[\text{NO}_2] \cdot J(\text{NO}_2)$ was obtained, and then the three additional HONO sources (i.e., the $P_{\text{unknown}}$, HONO emissions and nighttime hydrolysis conversion of NO$_2$ on aerosols) were inserted into the WRF-Chem model, to assess the $P_{\text{unknown}}$ impacts on the concentrations and budgets of HONO and RO$_x$ in the coastal regions of China. The results showed that:

- The additional HONO sources led to significant improvements in the simulations of HONO and OH, especially in the daytime.

- Elevated daytime average $P_{\text{unknown}}$ values were found in the coastal regions of China, reaching 2.5 ppb h$^{-1}$ in the BTH region, 2.0 ppb h$^{-1}$ in the YRD region, and 1.2 ppb h$^{-1}$ in the PRD region.
The additional HONO sources substantially enhanced the production and loss rates of HONO. Dry deposition of HONO contributed 0.28–0.45 ppb h⁻¹ to the loss rate of HONO, approximately equivalent to the contribution of HONO emissions, emphasizing the importance of dry deposition of HONO in high NO₂ emissions areas. Overall, the above results suggest that the $P_{\text{unknown}}$ significantly enhances the atmospheric oxidation capacity in the coastal regions of China by increasing RO₂ concentrations and accelerating RO₂ cycles, and could lead to considerable increases in concentrations of inorganic aerosols and secondary organic aerosols and further aggravate haze events in these regions.
