Abstract. The Pacific–North America teleconnection (PNA) is the leading general circulation pattern in the troposphere over the region of North Pacific to North America during wintertime. This study examined the impacts of monthly variations of the PNA phase (positive or negative phase) on wintertime surface-layer aerosol concentrations in the United States (US) by analyzing observations during 1999–2013 from the Air Quality System of the Environmental Protection Agency (EPA-AQS) and the model results for 1986–2006 from the global three-dimensional Goddard Earth Observing System (GEOS) chemical transport model (GEOS-Chem). The composite analyses on the EPA-AQS observations over 1999–2013 showed that the average concentrations of PM$_{2.5}$, sulfate, nitrate, ammonium, organic carbon, and black carbon aerosols over the US were higher in the PNA positive phases (25 % of the winter months examined, and this fraction of months had the highest positive PNA index values) than in the PNA negative phases (25 % of the winter months examined, and this fraction of months had the highest negative PNA index values) by 1.0 µg m$^{-3}$ (8.7 %), 0.01 µg m$^{-3}$ (0.5 %), 0.3 µg m$^{-3}$ (29.1 %), 0.1 µg m$^{-3}$ (11.9 %), 0.6 µg m$^{-3}$ (13.5 %), and 0.2 µg m$^{-3}$ (27.8 %), respectively. The simulated geographical patterns of the differences in concentrations of all aerosol species between the PNA positive and negative phases were similar to observations. Based on the GEOS-Chem simulation, the pattern correlation coefficients were calculated to show the impacts of PNA-induced variations in meteorological fields on aerosol concentrations. The PNA phase was found (i) to influence sulfate concentrations mainly through changes in planetary boundary layer height (PBLH), precipitation (PR), and temperature; (ii) to influence nitrate concentrations mainly through changes in temperature; and (iii) to influence concentrations of ammonium, organic carbon, and black carbon mainly through changes in PR and PBLH. Results from this work have important implications for the understanding and prediction of air quality in the US.

1 Introduction

Aerosols are the major air pollutants that have adverse effects on human health, reduce atmospheric visibility, and influence climate through aerosol–radiation and aerosol–cloud interactions (IPCC, 2013). Aerosol concentrations are high over the industrialized regions such as the United States (US), Europe, and East Asia, which are driven by emissions of aerosols and aerosol precursors (Dutkiewicz et al., 2000; Vestreng et al., 2007; Hand et al., 2012a; Mijling et al., 2013) and regional meteorological conditions.
Previous studies have shown that aerosol concentrations are very sensitive to meteorological parameters (Aw and Kleeman, 2003; Wise and Comrie, 2005; Dawson et al., 2007; Kleeman, 2008; Jacob and Winner, 2009; Tai et al., 2010, 2012a; Allen et al., 2015; Markakis et al., 2015; Megaritis et al., 2014; Porter et al., 2015). Aw and Kleeman (2003) examined the sensitivity of PM$_{2.5}$ (aerosol particles with a diameter $\leq 2.5 \mu m$) concentration to temperature by performing sensitivity studies in the California Institute of Technology/UC Davis (CIT/UCD) air quality model. A cross-board increase in temperature by 5 K in southern California on 25 September 1996, led to decreases in peak PM$_{2.5}$ concentrations by up to 30.7 $\mu g m^{-3}$ (30%). Wise and Comrie (2005) reported, by statistical analyses of observational data sets obtained from Air Quality System of the US Environmental Protection Agency (EPA-AQS), that the variations in meteorological parameters accounted for 20–50 % of the variability in aerosol levels over 1990–2003 in five metropolitan areas in the southwestern US. They found that aerosols in these five cities were most sensitive to relative humidity. Dawson et al. (2007) found, by sensitivity studies in the Particulate Matter Comprehensive Air Quality Model with extensions (PMCAMx), that PM$_{2.5}$ concentrations in summer had a small sensitivity to temperature increases ($-16$ ng m$^{-3}$ K$^{-1}$ on average) because the increases in sulfate offset the decreases in nitrate and organics, while PM$_{2.5}$ concentrations in winter decreased significantly with temperature ($-170$ ng m$^{-3}$ K$^{-1}$ on average) because the increases in temperature led to large reductions in nitrate and organics. Dawson et al. (2007) also showed that PM$_{2.5}$ concentrations increased with humidity in both winter and summer. Jacob and Winner (2009) summarized through literature review that the regional stagnation, mixing depth, and precipitation are the most important meteorological parameters that influence surface-layer aerosol concentrations. Future climate change was also simulated to influence aerosol levels over the US by $-1$ to $+1 \mu g m^{-3}$ (Jacob and Winner 2009), as a result of the climate-induced changes in atmospheric oxidants, transport, deposition, and the shift of gas–particle equilibria (Liao et al., 2006; Unger et al., 2006; Bauer et al., 2007; Jacob and Winner, 2009; Pye et al., 2009; Lam et al., 2011; Day and Pandis, 2011; Juda-Rezler et al., 2012; Tai et al., 2012b).

Previous studies have also reported that the changes in atmospheric circulation pattern and climate systems, such as the East Asian summer monsoon (EASM), North Atlantic Oscillation (NAO), El Niño–South Oscillation (ENSO), Atlantic Multidecadal Oscillation (AMO), and Arctic sea ice (ASI), can modulate distributions and concentrations of aerosols (Moulin et al., 1997; Singh and Palazoglu, 2012; Zhu et al., 2012; Jerez et al., 2013; Liu et al., 2013; Xiao et al., 2014; Wang et al., 2015). Zhu et al. (2012) found, by simulation of aerosol concentrations over years 1986–2006 with the global chemical transport model GEOS-Chem, that the decadal-scale weakening of the EASM led to increases in aerosol concentrations in eastern China, and summertime surface aerosol concentrations in the weakest EASM years were larger than those in the strongest EASM years by approximately 20 %. Moulin et al. (1997) showed that the variations in NAO could influence mineral dust aerosol transported to the North Atlantic Ocean and the Mediterranean Sea, since the mean aerosol optical depth (AOD) of dust in summer correlated with the NAO index during 1983–1994 with the correlation coefficients of 0.49 and 0.66, respectively. Jerez et al. (2013) found, by simulations of aerosols for years 1970–1999 with the CHIMERE chemistry transport model driven by the European Centre for Medium-Range Weather Forecasts Reanalysis data (ECMWF ERA-40), that the concentrations of PM$_{10}$ and PM$_{2.5}$ in European differed by 10 and 20 $\mu g m^{-3}$, respectively, between the positive and negative NAO phases. By using the multi-angle imaging spectroradiometer satellite (MISR) data sets of AOD during 2000–2011, Liu et al. (2013) found a period of 3–4 years in observed summertime AOD over the North China Plain (NCP), and the peak of summertime AOD in NCP occurred 4 months later after the rapidly transition of El Niño from a warm phase to a cold phase because of the associated cyclone anomaly and maritime inflow over the NCP. Singh and Palazoglu (2012) found correlations between Pacific Decadal Oscillation (PDO) and ENSO and the aerosol exceedance days (defined as the days with PM$_{2.5}$ concentrations larger than the US National Ambient Air Quality Standard) at 6 regions in the US by using the EPA-AQS PM$_{2.5}$ wintertime data sets during 1950–2008.

The Pacific–North America teleconnection pattern (PNA) is one of the most recognized, influential climate patterns in the mid-latitudes over the region of North Pacific to North America during wintertime with monthly variations (Wallace and Gutzler, 1981; Blackmon et al., 1984; Liang et al., 2005; Atlantasiadis and Ambaum, 2009). The PNA phase is defined by the geopotential height anomalies in the middle troposphere over the vicinity of Hawaii, the south of the Aleutian Islands, the intermountain region of North America, and the Gulf Coast region in the US (Wallace and Gutzler, 1981). A positive (negative) PNA phase is characterized by positive (negative) geopotential height anomalies over the vicinity of Hawaii and the northwestern North America, whereas it is characterized by negative (positive) geopotential height anomalies over south of the Aleutian Islands and the Gulf Coast region (see Fig. S1 in the Supplement).

The PNA has large impacts on surface-layer meteorological variables in the US during wintertime. Previous studies have reported a strong positive (negative) correlation between PNA and surface ambient temperature in the northwestern (southeastern) US (Leathers et al., 1991; Redmond and Koch, 1991; Liu et al., 2015), and a negative correlation between PNA and precipitation rate (Leathers et al., 1991; Coleman and Rogers, 2003; Ning and Bradley, 2014, 2015) and moisture (Coleman and Rogers, 2003) in the contiguous Ohio River Valley. These variations in meteorological
parameters in the US are associated with the PNA-induced anomalies in jet stream position, activities of cold fronts, and synoptic cyclones (Leathers et al., 1991; Notaro et al., 2006; Myoung and Deng, 2009).

Several studies have examined the impacts of PNA on aerosols. Gong et al. (2006) studied the interannual variations in the trans-Pacific transport of Asian dust during 1960–2003 by using the northern aerosol regional climate model (NARCM). They found a negative correlation (with a correlation coefficient of $-0.55$) between the PNA and the ratio of dust mass that reached the North American continent to that exported from Asia because of the strong westerly jet in the East Pacific during the negative PNA phases. Di Pierro et al. (2011), by using satellite retrieval of aerosol optical depth (AOD) from Cloud–Aerosol Lidar with Orthogonal Polarization (CALIOP), identified 11 events of Asian aerosol transport to the Arctic during 2007 to 2009, in which four events were associated with the negative PNA phases. These studies, however, were focused on the impact of PNA on the transport of aerosols due to the variations in westerly jet stream and blocking activity. Furthermore, these studies were limited to aerosols in the regions of North America and the Arctic.

We examine in this work the impacts of monthly variations in PNA phase on aerosol concentrations in the US during wintertime, by analyses of the observed aerosol concentrations during 1999–2013 from EPA-AQS and also by simulations of aerosol concentrations for years 1986–2006 using the global chemical transport model GEOS-Chem. The scientific goals of this work are (1) to quantify the differences in aerosol concentrations in month $j$ of year $i$, $n$, is the number of years examined. Such a deseaslonality approach was used in previous studies that examined the monthly variations in mineral dust aerosol (Cakmur et al., 2001; Mahowald et al., 2003), the decreasing trends in observed PM$_{2.5}$ concentrations and satellite AOD in the southeastern US over 2000–2009 (Alston et al., 2012), and the monthly variations in global AOD (Li et al., 2013). (3) Since the observed aerosol concentrations exhibited a significant decreasing trend from 1999 to present in the US due to the reductions in emissions of aerosols and aerosol precursors (Alston et al., 2012); http://www3.epa.gov/airtrends/aqtrends.html#comparison), the long-term linear trend in concentrations is identified by the least-square fit and then removed from the wintertime observed concentrations for each site. The EPA-AQS sites with measurements that meet the criteria described in (1) are shown in Fig. 1.

![Figure 1. The locations of EPA-AQS sites with measurements that meet the criteria described in Sect. 2.1 in the text. PM$_{2.5}$ measurements are available for the years 1999–2013 (sites are marked by black dots) and speciated aerosol (SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC, and OC) concentrations are available over years of 2000–2013 (sites are marked by red diamonds). The grey solid line defines the western US (west of 100° W) and eastern US (east of 100° W).](image-url)
2.2 GEOS-Chem simulation

We also examine the impacts of PNA on simulated aerosol concentrations in the US by using the GEOS-Chem model (version 8-2-1; http://acmg.seas.harvard.edu/geos). The GEOS-Chem model is a global chemical transport model driven by the assimilated meteorological fields from the Goddard Earth Observing System (GEOS) of the NASA Global Modeling and Assimilation Office (GMAO). The version of the model we use has a horizontal resolution of $2\degree \times 2.5\degree$ and 30 hybrid $\sigma$-pressure layers from the surface to 0.01 hPa altitude. The model has a fully coupled simulation of tropospheric $\text{O}_3-\text{NO}_x-\text{VOC}$ (volatile organic compound) chemistry and aerosols including $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, BC, OC (Park et al., 2003, 2004), mineral dust (Fairlie et al., 2007), and sea salt (Alexander et al., 2005). Considering the large uncertainties in chemistry schemes of secondary organic aerosol (SOA), SOA in our simulation is assumed to be the 10% carbon yield of OC from biogenic terpenes (Park et al., 2003) and 2% carbon yield of OC from biogenic isoprene (van Donkelaar et al., 2007; Mu and Liao, 2014). We mainly examine simulated anthropogenic aerosols from the GEOS-Chem simulation, since mineral dust concentrations in winter are very small (Malm et al., 2004; Zhang et al., 2013) and sea salt is not a major aerosol species in the US (Malm et al., 2004).

The model uses the advection scheme of Lin and Rood (1996), the deep convective scheme of Zhang and McFarlane (1995), the shallow convection scheme of Hack (1994), the wet deposition scheme of Liu et al. (2001), and the dry deposition scheme of Wesely (1989) and Wang et al. (1998). The instantaneous vertical mixing in the planetary boundary layer (PBL) is accounted for by the TURBDAY mixing scheme (Bey et al., 2001). The average PBL height in wintertime in the US is about 480 m and occupies the lowest 3–6 vertical model layers.

We simulate aerosols for the years 1986–2006 driven by the GEOS-4 reanalysis data. The years of 1986–2006 are chosen for chemistry–aerosol simulation because these are the years that the GEOS-4 data sets are available. Global anthropogenic emissions are from the Global Emissions Inventory Activity (GEIA) (Park et al., 2004, 2006; Zhu et al., 2012; Yang et al., 2015). Anthropogenic emissions over the US are overwritten by the US EPA National Emission Inventory Activity (NEI99), which have monthly variations in emissions of precursors including $\text{SO}_2$, $\text{NO}_x$, and $\text{NH}_3$. Monthly biomass burning emissions are taken from the Global Fire Emissions Database version 2 (GFED-2) (Giglio et al., 2006; van der Werf et al., 2006). During the simulation of aerosols for the years 1986–2006, the global anthropogenic and biomass burning emissions of aerosols and aerosol precursors are fixed at year 2005 levels, so that the variations in aerosol concentrations are caused by variations in meteorological parameters alone. non-methane volatile organic compounds (NMVOCs) and $\text{NO}_x$ from lightning and soil, are allowed to vary over 1986–2006 following the variations in the GEOS-4 meteorological parameters. Biogenic NMVOC emissions are calculated using the module of Model of Emissions of Gases and Aerosols from Nature (MEGAN) (Guenther et al., 2006). Lightning $\text{NO}_x$ emissions are described by Sauvage et al. (2007) and Murray et al. (2012). Soil $\text{NO}_x$ emissions are calculated using the algorithm proposed by Yienger and Levy (1995).

The GEOS-Chem simulation of aerosols in the US have been evaluated extensively by previous studies (Park et al., 2003, 2004, 2005; Heald et al., 2006, 2008; van Donkelaar et al., 2006, 2008; Liao et al., 2007; Fu et al., 2009; Drury et al., 2010; Leibensperger et al., 2011; Zhang et al., 2012). These studies have shown that the GEOS-Chem model can capture the magnitudes and distributions of aerosols in the US. The OH concentrations in GEOS-Chem were examined by previous studies (Holmes et al., 2013; Wu et al., 2007) by calculating the methane lifetime, which agreed closely with the lifetime of $11.2 \pm 1.3$ years constrained by methyl chloroform observations by Prather et al. (2012). Previous studies also showed that aerosol concentrations were not so sensitive to OH concentrations in the GEOS-Chem simulations (Heald et al., 2012).

2.3 PNA index

The PNA index (PNAI) is commonly used to quantify the changes in PNA phase (Wallace and Gutzler, 1981; Leathers et al., 1991). This study follows the definition of PNAI by Leathers et al. (1991). In order to examine the monthly variations in PNA, the mean seasonal cycle of geopotential height at 700 hPa is removed for the months of November, December, January, February, and March (NDJFM) in the studied years. Such a deseasonality approach has been used in the analyses of the growth and decay of the PNA phase in NDJFM (Feldstein, 2002), the development of NAO (Feldstein, 2003), the influence of NAO on precipitation in Europe (Qian et al., 2000), and the variations in Madden–Julian oscillation (Wheeler and Hendon, 2004). If we are concerned with the PNAI during $n$ years, the monthly PNAI in month $j$ ($j$ is one of the 5 months of NDJFM) of year $i$ is calculated by

$$\text{PNAI}_i = \frac{1}{3} \left[ -Z_{i,j}^* \left( 47.9^\circ \text{N}, 170^\circ \text{W} \right) + Z_{i,j}^* \left( 47.9^\circ \text{N}, 110^\circ \text{W} \right) - Z_{i,j}^* \left( 29.7^\circ \text{N}, 86.3^\circ \text{W} \right) \right] $$

(1)

where $Z_{i,j}^*$ is the removal of seasonal cycle, and $Z_{i,j}^*$ denotes the standardized anomaly of geopotential height at 700 hPa in month $j$ of year $i$ with seasonal cycle removed.

The PNAI is calculated by using both the National Center of Environmental Prediction – Department of Energy Reanalysis 2 data (NCEP-2; horizontal resolu-
J. Feng et al.: Impact of the PNA pattern on wintertime aerosols in the US

3 Impacts of PNA on observed aerosol concentrations

The measurements of PM$_{2.5}$ are available over 1999–2013, in which there were 18 PNA+ months and 18 PNA− months as shown in Fig. 2a. Figure 3 shows the differences in observed surface-layer PM$_{2.5}$ concentrations between the PNA+ and PNA− months (concentrations averaged over the 18 PNA+ months minus those averaged over the 18 PNA− months). The uncertainty associated with the differences in aerosol concentrations between PNA+ and PNA− months is represented by the two-tail Student t test with significance level of 90%. Among 1044 sites with PM$_{2.5}$ concentrations (Fig. 1), 42% of which had statistically significant differences in PM$_{2.5}$ between PNA+ and PNA− months. Relative to the PNA− months, PM$_{2.5}$ concentrations in PNA+ months were higher in California, the contiguous Salt Lake (northern Utah), and over and near the eastern Midwest. The maximum enhancement of PM$_{2.5}$ reached 7–9 µg m$^{-3}$ (or 40–80%) in California, 7–9 µg m$^{-3}$ (80–100%) around Salt Lake, 3–5 µg m$^{-3}$ (40–80%) over and near the eastern Midwest. At sites in North Dakota, Wisconsin, Michigan, Minnesota, Montana, Texas, and Maine, the PM$_{2.5}$ concentrations were lower by up to 2 µg m$^{-3}$ (10 to 20%) in PNA+ months than in PNA− months. As the concentrations are averaged over all sites (including the sites that pass and do not pass the t test with 90% confidence level) in the US, the western US (west of 100° W, Fig. 1), and the eastern US (east of 100° W, Fig. 1), PM$_{2.5}$ concentrations were higher by 1.0 µg m$^{-3}$ (8.7%), 1.3 µg m$^{-3}$ (14.3%), and 0.8 µg m$^{-3}$ (7.2%), respectively, in the PNA+ months than in PNA− months (Table 1). The measurements of speciated aerosols are available during 2000–2013, in which there were 17 PNA+ and 17 PNA− months (Fig. 2b). Figure 3 also shows the differences in observed surface-layer concentrations of individual aerosol species between the PNA+ and PNA− months. The dif-

The $^a$ and $^b$ indicate the differences that have passed the two-tail student t test with 90% and 95% significance levels, respectively.

Table 1. The absolute (µg m$^{-3}$) and relative (%) differences in observed aerosol concentrations between the PNA+ and PNA− months (PNA+ minus PNA−). The observed concentrations are averaged over all the sites in the whole of US, in the western US, or in the eastern US. See Fig. 1 for locations of the sites. The measurements are from the EPA-AQS data.
...ences in concentrations of SO$_2$$^-$$^-$, NO$_3$$^-$$^-$$^-$, and NH$_4$$^+$ show statistically significant positive values at most sites. Among the 355, 343, and 194 sites with measurements of SO$_2$$^-$$^-$, NO$_3$$^-$$^-$$^-$, and NH$_4$$^+$, 30, 44, and 39 % of which pass the two-tail t test with 90 % confidence level, respectively. While the absolute differences in concentrations of SO$_2$$^-$$^-$, NO$_3$$^-$$^-$$^-$, and NH$_4$$^+$ between PNA$^+$ and PNA$^-$ were in the range of 0–1 $\mu$g m$^{-3}$ at most sites, the maximum differences reached 1.5–2.5 $\mu$g m$^{-3}$ (30–50 %) for SO$_2$$^-$$^-$ in Pennsylvania, 1.5–2.5 $\mu$g m$^{-3}$ (150–200 %) for NO$_3$$^-$$^-$$^-$ in Illinois, Indiana, and Ohio, and 1.5–2.5 $\mu$g m$^{-3}$ (50–70 %) for NH$_4$$^+$ in Pennsylvania. Averaged over the sites with measurements, the absolute differences in concentrations of SO$_2$$^-$$^-$ and NO$_3$$^-$$^-$$^-$ between PNA$^+$ and PNA$^-$ months were larger in the eastern US than in the western US. As shown in Table 1, the differences in the averaged concentrations of SO$_2$$^-$$^-$, NO$_3$$^-$$^-$$^-$, and NH$_4$$^+$ were, respectively, 0.1 $\mu$g m$^{-3}$ (3.7 %), 0.4 $\mu$g m$^{-3}$ (36.5 %), and 0.1 $\mu$g m$^{-3}$ (10.5 %) in the eastern US, 0.03 $\mu$g m$^{-3}$ (3.2 %), 0.2 $\mu$g m$^{-3}$ (23.8 %), and 0.2 $\mu$g m$^{-3}$ (31.6 %) in the western US, as well as 0.01 $\mu$g m$^{-3}$ (0.5 %), 0.3 $\mu$g m$^{-3}$ (29.1 %), and 0.1 $\mu$g m$^{-3}$ (11.9 %) in the whole of US.

With regard to carbonaceous aerosols, among the 105 and 104 sites with measurements of OC and BC, 39 and 31 % of which pass the two-tail t test with 90 % confidence, respectively, the differences in concentrations of these two species between PNA$^+$ and PNA$^-$ months show similar geographical pattern, with positive values at most sites but negative values in Michigan, New York, and the south Atlantic states. The maximum differences between the PNA$^+$ and PNA$^-$ months reached 2.5–3 $\mu$g m$^{-3}$ (50–70 %) in Kentucky for OC. Averaged over sites with measurements available, the absolute differences in OC and BC concentrations between the PNA$^+$ and PNA$^-$ months were larger in the western US than in the eastern US (Table 1). Among all aerosol species listed in Table 1, OC exhibited the largest absolute differences between the PNA phases in the western US, because OC accounts for 25–65 % of PM$_{2.5}$ in the western US (Malm et al., 2004) and the OC observed by EPA-AQS network, which are located in urban and suburban settings, were higher than the observations by other long-term networks in US (Malm et al., 2011; Rattigan et al., 2011, Hand et al., 2012b, 2014).

Observations from EPA-AQS data sets indicate the large impacts of PNA phase on aerosol concentrations in the US. It should be noted that, in our analyses above, the locations of measurements and the numbers of samples were different for different aerosol species. The regional averages were also influenced by the uneven distributions of observational sites in different regions. Therefore, model results from the GEOS-Chem simulation will be used to further analyze the impacts of PNA on aerosols in the US, as presented in the subsequent sections.

We have also calculated the correlation coefficient between PNAI and EPA-AQS surface aerosol concentrations at each site for each aerosol species (PM$_{2.5}$, SO$_2$$^-$$^-$, NO$_3$$^-$$^-$$^-$, NH$_4$$^+$, OC, or BC) (see Fig. S2). About 40, 30, 47, 33, 33, and 34 % of sites pass the two-tail t test with 90 %
confidence for PM$_{2.5}$, SO$_2$,$^-$, NO$_3^-$, NH$_4^+$, OC, and BC, respectively. At most sites, positive (negative) correlation coefficients in Fig. S2 corresponded to the increases (decreases) in aerosol concentration in PNA+ months relative to PNA− months shown in Fig. 3. Positive correlation coefficients were large over California, the contiguous Salt Lake, and over and near the eastern Midwest. The fraction of temporal variability explained by PNA (FTVEP) can be quantified approximately by the square of correlation coefficient (http://mathbits.com/MathBits/TISection/Statistics2/correlation.htm) (see Fig. S3). For all aerosol species, FTVEP values were about 5–15 % at most sites. For PM$_{2.5}$, SO$_2$,$^-$, NO$_3^-$, and NH$_4^+$ aerosols, FTVEP values were high over and near the eastern Midwest, where the PNA teleconnection explained up to 50, 40, 50, and 40 % of temporal variances of surface concentrations of these aerosol species, respectively.

4 Impacts of PNA on simulated aerosol concentrations

4.1 Simulated aerosol concentrations and model evaluation

Figure 4a shows the simulated surface-layer concentrations of PM$_{2.5}$ (the sum of SO$_2$,$^-$, NO$_3^-$, NH$_4^+$, BC, and OC) and each aerosol species averaged over NDJFM of 1999–2006. These years are selected because they are the common years of model results and EPA-AQS observation data sets. The simulated PM$_{2.5}$ concentrations were higher in the eastern US than in the western US. The maximum surface PM$_{2.5}$ concentrations reached 14–16 µg m$^{-3}$ in Ohio and Pennsylvania. PM$_{2.5}$ concentrations in the western US were generally less than 4 µg m$^{-3}$, except for California where PM$_{2.5}$ concentrations were 2–6 µg m$^{-3}$. The distribution of SO$_2$,$^-$ was similar to that of PM$_{2.5}$, with higher concentrations in the eastern US (1–8 µg m$^{-3}$) than in the western US (0–3 µg m$^{-3}$) due to the coal-fired power plants in the Midwest (Park et al., 2006). The concentrations of NO$_3^-$ and NH$_4^+$ were the highest over and near the eastern Midwest, with values of 3–4 and 2–3 µg m$^{-3}$, respectively. The maximum OC concentrations were simulated to be 2–3 µg m$^{-3}$ in two regions, from Ohio to Massachusetts and from Alabama to South Carolina. The simulated BC concentrations in the US were 0–1 µg m$^{-3}$, except for the contiguous New York where BC concentrations reached 1–2 µg m$^{-3}$. The magnitudes and geographic distributions of SO$_2$,$^-$, NO$_3^-$, NH$_4^+$ concentrations simulated in our work are similar to those simulated by Park et al. (2006) and Pye et al. (2009), and our simulated OC and BC were similar to those reported by Park et al. (2003).

Figure 4b presents the scatter plots of the simulated concentrations versus the EPA-AQS observations. The simulated PM$_{2.5}$ concentrations had normalized mean bias (NMB = $\sum_{m=1}^{M}(S_m - O_m)/\sum_{m=1}^{M}(O_m) \times 100\%$, where $S_m$ and $O_m$ are the simulated and observed aerosol concentrations in month $m$, respectively. $M$ is the total number of winter months examined) of $-30\%$ over the US, and the correlation coefficient between simulated and observed PM$_{2.5}$ concentrations was 0.57. The simulated wintertime SO$_2$,$^-$, NO$_3^-$, and NH$_4^+$ had NMBs of 37, 4, and 26 %, respectively. Similar bias in simulated SO$_2$,$^-$ in December–January–February (DJF) was reported Park et al. (2006), as the GEOS-Chem model results were compared with observations from the Clean Air Status and Trends Network (CASTNET). The high bias in our simulated NH$_4^+$ was associated with the overestimation
of $\text{SO}_4^{2-}$. Our model underestimates $\text{PM}_{2.5}$, $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, OC, and BC in the western US (Fig. 4b), which can be explained in part by the relatively high aerosol concentrations observed for this region from the EPA-AQS. Hand et al. (2014) compared the observed concentrations of aerosols from the EPA-AQS with those from the Interagency Monitoring of Protected Visual Environments (IMPROVE) for 2008–2011, and showed that the ratios of wintertime aerosol concentrations of ammonium sulfate, ammonium nitrate, OC, and BC from the EPA-AQS to those from the IMPROVE were, respectively, 2.3, 7.7, 8.3, and 13.1, as the concentrations were averaged over the western US. Liu et al. (2004) also attributed the high EPA-AQS concentrations in the western US to the relative sparse urban sites that were heavily influenced by strong local sources such as automobiles and wood fires. The low model biases in the western US may also be caused by the biases in emissions in the model.

Since this study is dedicated to examine the influence of PNA phase on the month-to-month variations of aerosol concentrations during wintertime, Fig. 4c compares, for each aerosol species, the deviation from the mean (DM) of observed concentration with that of simulated concentration for each winter month. The DM is defined as $\text{DM}_m = \frac{\left(C_m - \frac{1}{M} \sum_{m=1}^{M} C_m\right)}{\frac{1}{M} \sum_{m=1}^{M} C_m}$, where $C_m$ is the simulated average aerosol concentration over the US in month $m$, and $M$ is the number of winter months examined (we consider the months of NDJFM over 1999–2006 for $\text{PM}_{2.5}$, and the months of NDJFM over 2000–2006 for $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, BC, and OC). The model captures fairly well the peaks and troughs of DMs for $\text{PM}_{2.5}$, $\text{SO}_4^{2-}$, $\text{NO}_3^-$, and $\text{NH}_4^+$, with correlation coefficients of 0.61, 0.45, 0.33, and 0.65, respectively. The model does not capture well the monthly variations of DMs of concentrations of OC and BC, because both anthropogenic and biomass burning emissions are fixed at year 2005 levels during our simulation over 1986–2006 to isolate the impacts of variations in meteorological parameters (PNA phases) on aerosols (see Sect. 2.2). Since the biomass burning emissions, which contribute largely to carbonaceous aerosols, have large interannual variations (Duncan et al., 2003; Generoso et al., 2003; van der Werf et al., 2006), we also show in Fig. 4c the time series of DMs of biomass burning emissions of OC and BC by using biomass burning emissions in NDJFM over 2000–2006 from GFED v2. The correlation coefficients between biomass burning emissions and observed concentrations of OC and BC were 0.36 and 0.34, respectively, indicating that the observed variations in OC and BC were influenced by monthly and interannual variations in biomass burning. We have also calculated the temporal correlation coefficient between EPA-AQS observations and GEOS-Chem model results at each site for each aerosol species (Fig. S4). The temporal correlations were statistically significant for $\text{PM}_{2.5}$, $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$ at most sites in the US, especially over and near the eastern Midwest where largest increases in aerosol concentrations were identified in the PNA+ months relative to the PNA− months.

### 4.2 Impact of PNA on simulated surface-layer aerosol concentrations

We have performed the GEOS-Chem simulation for the years 1986–2006, in which there were 35 PNA+ and 35 PNA− months (Fig. 2). Figure 5a shows the concentrations of $\text{PM}_{2.5}$ and each aerosols species averaged over the PNA− months of 1986–2006. (b) The absolute differences ($\mu\text{g m}^{-3}$) in simulated aerosol concentrations between PNA+ and PNA− months (PNA+ minus PNA−). (c) The relative differences (%) in simulated aerosol concentrations between PNA+ and PNA− months. The white spaces in (c) indicate the areas that did not pass the two-tail student $t$ test with 90% significance level. The seasonal cycles of simulated aerosol concentrations were removed. See Fig. 2c for the definitions of PNA+ and PNA− months.

Figure 5. (a) Simulated concentrations ($\mu\text{g m}^{-3}$) of $\text{PM}_{2.5}$ and each aerosols species averaged over the PNA− months of 1986–2006. (b) The absolute differences ($\mu\text{g m}^{-3}$) in simulated aerosol concentrations between PNA+ and PNA− months (PNA+ minus PNA−). (c) The relative differences (%) in simulated aerosol concentrations between PNA+ and PNA− months. The white spaces in (c) indicate the areas that did not pass the two-tail student $t$ test with 90% significance level.
The differences in concentrations of SO$_2$ and NO$_x$ within the southeastern US, because the model does not capture PNA and NH$_4^+$ over the eastern US in PNA+ months relative to PNA− months (Table 2). The simulated relative difference in PM$_{2.5}$ was close to that from observations (Table 1) in the western US, but the simulated relative differences in PM$_{2.5}$ were larger than those from observations in the eastern and whole of US.

Figure 5 also shows the differences in simulated surface-layer concentrations of SO$_2^-$, NO$_3^-$, and NH$_4^+$ between the PNA+ and PNA− months. The differences in concentrations of SO$_2^-$ were larger in the western than in the eastern US, with maximum enhancements of 0.4–0.8 µg m$^{-3}$ (30–50 %) over the western north-central states (South Dakota, Nebraska, Minnesota, Iowa, and Missouri). The differences in concentrations of NO$_3^-$ and NH$_4^+$ between PNA+ and PNA− months had similar geographical patterns, with increases in concentrations in a large fraction of the eastern US and over a belt region along the Rocky Mountains in the western US. The increases in concentrations of NO$_3^-$ and NH$_4^+$ over the eastern US in PNA+ months relative to PNA− months agreed very well with those seen in observations in most regions of the US (Fig. 3). The model underestimates the differences in NO$_3^-$ in California and the southeastern US, because the model does not capture well the temporal variations of NO$_3^-$ in these two regions (Fig. S4). The differences in concentrations of SO$_2^-$, NO$_3^-$, and NH$_4^+$ in the eastern US between the PNA+ and PNA− months were 0.2 µg m$^{-3}$ (4.0 %), 0.4 µg m$^{-3}$ (33.5 %), and 0.2 µg m$^{-3}$ (13.2 %), respectively (Table 2).

The differences in concentrations of OC and BC between PNA+ and PNA− months had similar geographical patterns, with large increases in concentrations over and near the eastern Midwest and the region from northwestern US to Texas. The maximum differences reached 0.2–0.4 µg m$^{-3}$ (10–20 %) and 0.1–0.2 µg m$^{-3}$ (20–30 %) in Illinois, Indiana, and Ohio for OC and BC, respectively. The magnitudes of the differences in OC and BC were statistically significant but were smaller than the observations (Tables 1 and 2). The absolute differences in OC were less than 0.1 µg m$^{-3}$ in the western, eastern, and whole of US due to the underestimation of OC in the simulation.

In summary, model results agreed with observations in that the concentrations of all aerosol species of SO$_2^-$, NO$_3^-$, NH$_4^+$, BC, and OC averaged over the US were higher in PNA+ months than in PNA− months. Relative to the PNA− months, the average concentration of PM$_{2.5}$ over the US was higher by about 8.7 % (12.2 %) based on observed (simulated) concentrations. Furthermore, simulated geographical patterns of the differences in PM$_{2.5}$ and each aerosol species between the PNA+ and PNA− months were similar to those seen in observations in most areas of the US (except for California), with the largest increases in aerosol concentrations in PNA+ months over and near the eastern Midwest.

5 Mechanisms for the impact of PNA on aerosol concentrations

5.1 The impact of PNA on transboundary transport of aerosols

The transboundary transport of pollutants to and from the US depends largely on winds in the free troposphere (Liang et al., 2004). Figure 6 shows the horizontal winds at 700 hPa averaged over the winter months of NDJFM of 1986–2006 and the corresponding differences between PNA+ and PNA− months on the basis of the GEOS-4 meteorological fields. Strong westerlies prevailed over the US in wintertime (Fig. 6a). Relative to the PNA− months, anomalous northeasterlies occurred over a large fraction of US in the PNA+ months. Anomalous anti-cyclonic circulation occurred near the northwestern US and anomalous cyclonic circulation occurred near the southeastern US (Fig. 6b), corresponding to the large positive and negative differences in geopotential height in these two regions (see Fig. S1), respectively.

We also calculate mass fluxes of PM$_{2.5}$ at the four lateral boundaries (from the surface to 250 hPa) of the US for different PNA phases (Table 3). The domain of the box to represent the US is (75–120° W, 28–49° N), as shown in Fig. 6b. For PM$_{2.5}$ in wintertime, the inflow from the west boundary and the outflow from the east boundary had the largest absolute values (Table 3). Relative to the PNA− months,
the inflow from the west boundary and the outflow from the east boundary in PNA+ months exhibited reductions of 16.1 and 13.5 kg s\(^{-1}\), respectively (Table 3). The inflow flux from south boundary decreased by 15.8 kg s\(^{-1}\), and the inflow flux from north boundary increased by 31.7 kg s\(^{-1}\), leading to a net increase of inflow flux of 13.3 kg s\(^{-1}\) in PNA+ months. Therefore, the transboundary transport has an overall effect of increasing PM\(_{2.5}\) aerosols in the US in PNA+ months relative to PNA− months. The relative change in net flux was 9.9% ((PNA+ minus PNA−) × 100 %/PNA−) (Table 3), coinciding well with the enhancement of 12.2% in surface-layer PM\(_{2.5}\) concentration averaged over the US (Table 2). Note that because the GEOS-Chem model underestimates PM\(_{2.5}\) concentrations in the western US (Fig. 4b), the net outflow flux from the selected box might have been underestimated, but this should not compromise our conclusions about the relative differences in net flux between PNA+ and PNA− phases.

5.2 Local changes in aerosol concentrations caused by the PNA

The PNA pattern is also associated with variations in meteorological variables such as temperature (Leathers et al., 1991; Konrad II, 1998; Notaro et al., 2006; Knight et al., 2008; Liu et al., 2015; Ning and Bradley, 2014, 2015), precipitation (Leathers et al., 1991; Henderson and Robinson, 1994; Coleman and Rogers, 2003; Notaro et al., 2006; Archambault et al., 2008; Myoung and Deng, 2009; Ning and Bradley, 2014, 2015; Wise et al., 2015), and humidity (Sheridan, 2003; Coleman and Rogers, 2003; Knight et al., 2008) in US, which are expected to influence aerosol concentrations within the US through chemical reactions, transport, and deposition.

Figure 7 shows the composite differences, between the PNA+ and PNA− months, in surface air temperature (T), precipitation rate (PR), relative humidity (RH), surface wind speed (WS), and planetary boundary layer height (PBLH), based on the reanalyzed GEOS-4 data sets. Relative to PNA− months, temperatures were higher by 1–3 K over the northwestern US and lower by 1–4 K in the southeastern region. Such geographic distributions of temperature anomalies were attributed to the maritime warm air in the northwestern US accompanied by the enhanced tropospheric geopotential height in North America (Leathers et al., 1991; Sheridan, 2003; Liu et al., 2015; Ning and Bradley, 2015) (see also Fig. S1d) and the more frequent outbreak of cold air in southeastern US accompanied by the depressed geopotential height (Konrad II, 1998; Liu et al., 2015) (see also Table 3. The composite analyses of horizontal mass fluxes (kg s\(^{-1}\)) of PM\(_{2.5}\) for the selected box of (75–120° W, 28–49° N; from the surface to 250 hPa) in the PNA+ and PNA− months of 1986–2006. The positive values at the four boundaries indicate eastward or northward transport, and negative values indicate westward or southward transport. The positive (negative) value of net flux indicates the net gain (loss) of PM\(_{2.5}\) in the selected box. All the fluxes are from the GEOS-Chem simulation.

Fig. S1d). The differences in precipitation between PNA+ and PNA− months reached −1.6 to −2.4 mm day−1 (−32 to −48 %) over and near the eastern Midwest, −2.4 to −3.2 mm day−1 (−48 to −64 %) in the northwestern US, and 1.6–2.4 mm day−1 (16–32 %) in the southeastern US. These effects of PNA on precipitation were similar to those obtained from wintertime station data by Leathers et al. (1991), Coleman and Rogers (2003), and Wise et al. (2015). With respect to RH, the values in the eastern US were generally lower in the PNA+ months than in PNA− months, as a result of the reduced moisture flux from the Gulf of Mexico to the eastern US (Coleman and Rogers, 2003), where RH showed maximum reduction of −3 to −9 %. The enhancement of RH of up to −9 % in Texas, Oklahoma, and New Mexico was due to the anomalous easterlies over the south central US (see Fig. 7), which diminished the influence of the dry air from the deserts of the southwestern US and northwestern Mexico in PNA+ months (Sheridan, 2003). The surface WS showed reductions in PNA+ months relative to PNA− months in two regions, one was the belt region along the Rocky Mountains from the northwestern US to Texas (with the maximum reductions of 1.5–2.0 m s−1 (48–64 %)) and the other region, with a northeast–southwest orientation, was from Ohio to Louisiana (with maximum reductions of 0.5–1.0 m s−1 (16–32 %)). The differences in PBLH between PNA+ and PNA− months were statistically significant in the western US and in the belt region from the northeastern US to the eastern Midwest, with maximum reductions in PBLH of 75–100 m (15–20 %) and 75–100 m (10–15 %), respectively. The changes of PBLH were possibly associated with the frequent outbreak of cold air in the US in PNA+ phases (Leathers et al., 1991; Archambault et al., 2010), which induced cool air at the surface and clouds over the intermountain and the eastern Midwest regions (Sheridan, 2003).

The comparisons of Fig. 5b with Fig. 7a indicate that the increases in PM2.5 concentrations over and near the eastern Midwest in PNA+ months relative to the PNA− months can be attributed to the decreases in PR, WS, and PBLH in these locations, since the changes in these three variables depressed wet deposition, local horizontal diffusion, and vertical diffusion of the surface aerosols, respectively. The increases in SO2−4 in the western US (Fig. 5b) corresponded to the decreases in PR and PBLH and the increased temperature. The increases in temperature enhance chemical reaction rates (Aw and Kleeman, 2003; Dawson et al., 2007; Kleeman, 2008). In the eastern US, although PR, WS, and PBLH decreased over and near the eastern Midwest, the cooling in the eastern US might have offset the effects by PR, WS, and PBLH, inducing practically no changes in SO2−4 in the eastern US. The large increases in NO3− and NH4+ in the southeastern US (Fig. 5b) can be attributed to the reduced surface temperature, which was favorable to the wintertime formation of NO3− and NH4+ (Dawson et al., 2007). The differences in concentrations of OC and BC between PNA+ and PNA− corresponded well with the reduced PR, WS, and PBLH.

In order to quantify the impacts of anomalies in meteorological parameters driven by PNA on concentrations of different aerosol species, the pattern correlation coefficients (PCC; http://glossary.ametsoc.org/wiki/Pattern_correlation) are calculated and shown in Table 4. These pattern correlation coefficients denote the relationship between the geographical distribution of anomalies of each of T, PR, RH, WS, and PBLH (Fig. 7b) and that of the differences in concentration of each aerosol species between PNA+ and PNA− months (Fig. 5c). As shown in Table 4, over the whole US, the PNA influenced SO2−4 concentrations mainly
through changes in PBLH, PR, and T, with the highest PCC values of $-0.43$, $-0.38$, and $+0.26$, respectively. For NO$_3^-$, the PNA-induced variations in temperature had a strong negative correlation ($\text{PCC} = -0.59$) with the PNA-induced differences in concentrations, indicating that surface temperature was the dominant meteorological factor to influence NO$_3^-$ concentrations. For NH$_4^+$, OC, and BC, PR and PBLH were the two variables that had the largest negative PCC values (Table 4).

### 6 Conclusions

This study examined the impacts of monthly variation in the PNA phase on wintertime surface-layer aerosol concentrations in the US by the analyses of EPA-AQS observations over 1999–2013 and model results for 1986–2006 from the global chemical transport model GEOS-Chem.

The composite analyses on the EPA-AQS observations showed that the average concentrations of PM$_{2.5}$, SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, OC, and BC aerosols over the US were higher in the PNA+ months than in the PNA− months by $1.0 \mu g \text{ m}^{-3}$ (8.7 %), $0.01 \mu g \text{ m}^{-3}$ (0.5 %), $0.3 \mu g \text{ m}^{-3}$ (29.1 %), $0.1 \mu g \text{ m}^{-3}$ (11.9 %), $0.6 \mu g \text{ m}^{-3}$ (13.5 %), and $0.2 \mu g \text{ m}^{-3}$ (27.8 %), respectively. Regionally, the observed PM$_{2.5}$ concentrations were higher by 3–5 $\mu g \text{ m}^{-3}$ (40–80 %) over the Midwest, and by 7–9 $\mu g \text{ m}^{-3}$ (80–100 %) around Salt Lake, as the concentrations in PNA+ months were compared to those in PNA− months.

The impacts of PNA phase on aerosol concentrations were reproduced fairly well by the GEOS-Chem simulation with fixed anthropogenic emissions (the variations of aerosol concentrations were driven by changes in meteorological fields alone). Concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC, and OC averaged over the US were simulated to be higher in the PNA+ months than in PNA− months. The average concentration of PM$_{2.5}$ over the US was simulated to be 12.2 % higher in the PNA+ months relative to the PNA− months, in close agreement with the observations. Simulated geographical patterns of the differences in PM$_{2.5}$ and each aerosol species between the PNA+ and PNA− months were similar to those seen in observations. The largest increases in aerosol concentrations in the PNA+ months were simulated to be over and near the eastern Midwest, but the model results showed small PNA-induced changes in aerosol concentrations in the western US.

The mechanisms for the impacts of PNA on aerosol concentrations were examined. The transboundary transport was found to have an overall effect of increasing PM$_{2.5}$ aerosols in the US in the PNA+ months relative to PNA− months. Compared to the PNA− months, anomalous northeasterlies occurred over a large fraction of US, which led to a net increase in inflow flux of PM$_{2.5}$ of 13.3 Kg s$^{-1}$ in PNA+ months. Regionally within the US, the PNA influenced aerosol concentrations through changes in precipitation rate (PR), planetary boundary layer height (PBLH), surface wind speed (WS), surface air temperature (T), and relative humidity (RH), as represented by the pattern correlation coefficients (PCCs). The PNA influenced SO$_4^{2-}$ concentration mainly through changes PBLH, PR, and T, with the highest PCC values of $-0.43$, $-0.38$, and $+0.26$, respectively. For NO$_3^-$, the PNA-induced variations in temperature had a strong negative correlation ($\text{PCC} = -0.59$) with the PNA-induced differences in concentrations. For NH$_4^+$, OC, and BC, PR and PBLH were the two variables that had the largest negative PCC values. It should be noted that, the PCC values only statistically present the relationship between meteorological parameters and aerosol concentrations in the US. More in-depth understanding of the impact of PNA phase on aerosol concentrations should be carried out on the basis of physical and chemical processes.

Conclusions from this study have important implications for air quality in the US. Leathers and Palecki (1992) showed that the PNAI were generally low in 1947–1957 but consistently high in 1958–1987. The PNAI during 1948–2010 exhibited an increasing trend for positive phases and a decreasing trend for negative phases (Liu et al., 2015; Ning and Bradley, 2015; http://research.jisao.washington.edu/data_sets/pna/#djf), indicating that wintertime particulate matter pollution in most areas of US deteriorated due to variations in PNA phase alone. Climate models projected that positive PNA phases would increase in the future because of the global warming (Kachi and Nitta, 1997; Müller and Roeckner, 2008; Zhou, 2014). Therefore, the trend in PNA pattern underlies the necessity of strict emission reduction strategies for greenhouse gases, aerosols, and aerosol precursors.
