Abstract. Over 20 years of stratospheric NO\textsubscript{2} vertical column density (VCD) data from ground-based zenith DOAS spectrometers were used for trend analysis, specifically, via multiple linear regression. Spectrometers from the Network for the Detection of Atmospheric Composition Change (NDACC) cover the subtropical latitudes in the Northern Hemisphere (Izaña, 28°N), the southern Subantarctic (Ushuaia, 55°S) and Antarctica (Marambio, 64°S, and Belgrano, 78°S). The results show that for the period 1993–2014, a mean positive decadal trend of +8.7 % was found in the subtropical Northern Hemisphere stations, and negative decadal trends of −8.7 and −13.8 % were found in the Southern Hemisphere at Ushuaia and Marambio, respectively; all trends are statistically significant at 95 %. Belgrano only shows a significant decadal trend of −11.3 % in the summer/autumn period. Most of the trends result from variations after 2005. The trend in the diurnal build-up per hour (DBU) was used to estimate the change in the rate of N\textsubscript{2}O conversion to NO\textsubscript{2} during the day. With minor differences, the results reproduce those obtained for NO\textsubscript{2}. The trends computed for individual months show large month-to-month variability. At Izaña, the maximum occurs in December (+13.1 %), dropping abruptly to lower values in the first part of the year. In the Southern Hemisphere, the polar vortex dominates the monthly distributions of the trends. At Marambio, the maximum occurs in mid-winter (−21 %), whereas at the same time, the Ushuaia trend is close to its annual minimum (−7 %). The large difference in the trends at these two relatively close stations suggests a vortex shift towards the Atlantic/South American area over the past few years. Finally, the hemispheric asymmetry obtained in this work is discussed in the framework of the results obtained by previous works that considered tracer analysis and Brewer–Dobson circulation. The results obtained here provide evidence that the NO\textsubscript{2} produced by N\textsubscript{2}O decomposition is not the only cause of the observed trend in the stratosphere and support recent publications pointing to a dynamical redistribution starting in the past decade.

1 Introduction

Stratospheric nitrogen dioxide (NO\textsubscript{2}) has been a subject of interest since the late sixties, when the use of supersonic aircraft flying at stratospheric levels was being considered. At that time, studies on the impact of nitrogen oxides on the ozone in the stratosphere were initiated (Johnston, 1971). The interest in this atmospheric layer was enhanced in the mid-seventies, powered by the discovery of the ozone depletion potential of halogenated compounds (Stolarski and Cicerone, 1974).

Nitrogen oxides interact with ozone both directly and indirectly. Nitric oxide (NO) reacts with ozone, forming NO\textsubscript{2} and O\textsubscript{2}. NO is recovered by NO\textsubscript{2} reaction with atomic oxy-
gen and, in day time, by NO₂ photolysis. These catalytic re-
actions result in ozone reduction. On the other hand, NO₂ re-
acts with BrO and ClO, mitigating the ozone depletion po-
tential of halogenated compounds. NO₂ oxidation products,
such as HNO₃ and N₂O₅, have relatively long lifetimes and
therefore act as NO₂ reservoirs.

Regular monitoring of stratospheric NO₂ started in 1980
with the deployment of Zenith DOAS (Differential Optical
Absorption Spectroscopy) scanning spectrometers at Lauder,
New Zealand, by Mckenzie and Johnston (1982), followed
by two Antarctic stations (Scott Base at 78° S by Mcken-
zie and Johnston, 1984, and Dumont D’Urville at 66° S by
Pommerau and Goutail, 1988). In the following decades, in-
struments were installed at remote, unpolluted sites for mon-
itoring NO₂, O₃ and other stratospheric gases suitable for
ground-based measurements.

Recently, the interest in trends of stratospheric trace gases
has increased, since global circulation models predict an ac-
celeration of the stratospheric residual circulation (or Brewer–Dobson circulation, BDC hereafter) of 2–
3.2 % decade⁻¹ as a consequence of the temperature changes
in the atmosphere due to human activities (Butchart, 2014).
The speed of the BDC circulation influences the concen-
trations of long-lived trace gases with sources in the trop-
osphere (e.g. CFCs, CH₄, N₂O), as well as their eventual
stratospheric products (Cook and Roscoe, 2009). In partic-
ular, N₂O, which is the primary source of NO₁, disso-
ciates in the stratosphere via a reaction with excited atomic
oxygen (¹D) and produces NO. NO₂ is mainly formed by
the NO + O₃ reaction. An accelerated BDC implies a lower
mean residence time of N₂O in the stratosphere and, conse-
quently, a lower N₂O to NO₂ conversion.

On the other hand, the emissions of N₂O to the atmosphere
are steadily growing, with the concentration increasing at
a rate of 2.5 % decade⁻¹ and more in recent years (IPCC,
2013). Since the N₂O lifetime in the troposphere is approxi-
mately 120 years and N₂O is the major source of NO₂ in the
stratosphere, a tropospheric increase will result in an NO₂
increase in the stratosphere.

These two counteracting processes could minimise or even
cancel the potential changes in the stratospheric concentra-
tion of NO₂. However, the observational evidence of a trend
in the BDC speed remains inconclusive (Butchart, 2014; Fu
et al., 2015). Oberländer-Hayn et al. (2016) suggest that, even
though the stratosphere is changing substantially in response
to greenhouse gas (GHG) increases, most of the BDC trend
is associated with a lifting of the entire atmospheric circula-
tion instead of an accelerating flow. If this is the case, a NO₂
increase should be seen in the long term, given that all other
factors remain the same.

Previous studies to establish a trend in stratospheric NO₂
based on the DOAS data from the stations with long data
availability, however, did not yield conclusive results on the
global scale. A first attempt was undertaken by Liley et
al. (2000) using the longest data series available, who found
an approximately 5 % increase at Lauder (45° S) for the pe-
diod 1981–1999. Fish et al. (2000) found no explanation re-
lated to the changes in O₃, temperature or water vapour, con-
cluding that only changes in the stratospheric aerosol load
could explain the observations. Later, McLinden et al. (2001)
reproduced the observations of Liley et al. (2000) using a 3-
D CTM model, including halogen chemistry and assuming a
negative trend in temperature of 0.5 K decade⁻¹. A few years
later, Gruzdov (2009) analysed 23 stations from the NDACC
database. Trends were found to be mostly positive in the mid-
dle and low latitudes of the Southern Hemisphere (SH) and
mostly negative in the European sector of the middle lati-
tudes of the Northern Hemisphere (NH). In the high and po-
lar latitudes of both hemispheres, the annual estimates of the
trends were mostly statistically insignificant. In Antarctica, a
positive NO₂ trend was observed at 78° S, while at the NH
high latitudes, both positive and negative trends were ob-
served. A detailed study of the Jungfraujoch station (55° N,
3550 m a.s.l.), including DOAS plus FTIR data and satellite
composites (Hendrick et al., 2012), found negative trends
ranging from −2.4 to −4.3 %, depending on the instrument
and selected period. In summary, until now, the global NO₂
trend over the past few decades has not been accurately es-
stablished. One important difficulty in comparing the trends
at different latitudes is that the stations do not cover the same
periods. In addition, the trends can be the result of multiple
factors that do not behave linearly.

The purpose of this work is to contribute to the knowledge
of the long-term NO₂ evolution by searching for significant
trends in the stratospheric NO₂ using the INTA NO₂ DOAS
records in combination with a multiple regression model.
Such models have been extensively used in recent years to
infer trends in long-term atmospheric time series of ground-
based instruments; in particular, they have been used to study
the evolution of stratospheric ozone (Bodeker et al., 1998;
Wohltmann et al., 2007; Fioletov, 2008; Mäder et al., 2010),
NO₂ (Van der A et al., 2006, 2008; Gruzdov, 2009; Hendrick
et al., 2012) and other species (i.e. Remsberg, 2015).

The paper is organised as follows. In Sect. 2, the instru-
ments and data are described. In Sect. 3, the regression model
and explanatory variables are presented. Section 4 addresses
the results and is composed of three subsections. In Sect. 4.1,
the general results are shown. Section 4.2 addresses a more
detailed analysis of the subtropical case and, in Sect. 4.3, the
interhemispheric asymmetry is discussed. Finally, the con-
clusions are shown in Sect. 5.

2 Instrumentation, stations, techniques and database

In the year 1993, INTA installed a scanning spectrome-
ter at the subtropical high-mountain observatory of Izaña
(28° N, 16° W, 2370 m a.s.l.) for long-term measurements
of stratospheric NO₂. In 1994, two identical instruments
were deployed in the Subantarctic (Ushuaia station; 55° S,
68° W) and the Antarctic Peninsula (Marambio station; 64° S, 56° W). Then, in 1995, a fourth instrument was installed in Antarctica at a higher latitude (Belgrano station; 78° S, 35° W). The three instruments cover the latitudinal belt from the outside to the inside of the Antarctic vortex. Since installation, all instruments have been operated without interruption.

Belgrano (in continental Antarctica) is usually closest to the core of the polar vortex and hence is representative of the in-vortex air. Marambio (Antarctic Peninsula) is frequently located at the edge of the vortex region and alternates between measuring the vortex and the mid-latitude air masses. Ushuaia is, essentially, a mid-latitude station and only occasionally is reached by in-vortex air.

The instrumentation consists of spectrometers covering the visible range, and the retrieval is based on the DOAS technique. At all four stations, identical scanning spectrometers (EVA) were initially installed. In Izaña, a second spectrometer (RASAS), based on a diode array detector, covering a wider range, was added in 1999. Then, in 2010, the PDA was replaced by a CCD (RASAS-II) including MAXDOAS capability. All instruments were developed at the INTA laboratories. Data merging was carefully carried out after a period of overlap to ensure the smooth transition between the instruments. The transition between EVA and RASAS has been previously reported (Gil et al., 2008). The transition between RASAS and RASAS-II required a RASAS correction due to a degradation of the detector response since mid-2006, at a rate of 4.33 % year⁻¹. The details of the RASAS-II instrument have been previously published in Puentedura et al. (2012) and Robles-Gonzalez et al. (2016). The spectrometers were installed in the top terrace of the Izaña Atmospheric Observatory, run by the CIAI (Centro de Investigación Atmosférica de Izaña), belonging to the Agencia Estatal de Meteorología (AEMET, Spain), on the slopes of the Teide volcano, Tenerife, Canary Islands. The Izaña Atmospheric Observatory is a high mountain station, part of the Global Atmospheric Watch (GAW) programme and managed by the CIAI.

The EVA instrument is a scanning spectrometer for twilight measurements between 88 and 92° solar zenith angles (SZAs) in the 430–450 nm spectral range, with a spectral resolution of 1 nm. These instruments are located outdoors in thermostatic housings. The three Southern Hemisphere spectrometers were compared to each other after 1 year of measurements with the help of a NO₂ cell containing a known amount of gas. The discrepancies among them were found to be below 4 % (Yela et al., 2005). Twilight (AM – ante meridiem – and PM – post meridiem) vertical column densities were derived from all available measurements between 89 and 91° SZA, typically 5–6 data per twilight. New MAXDOAS instruments have been installed at the three stations, in 2011 at Belgrano, in 2015 at Marambio and in 2016 at Ushuaia. Both DOAS and MAXDOAS instruments simultaneously measure for data series homogenisation.

The NO₂ column retrieval is based on the standard DOAS spectral analysis (Platt and Stutz, 2008), performed using software developed at INTA. The DOAS settings for the NO₂ column retrieval follow the NDACC UV/Vis Working Group recommendations (Van Roozendael and Hendrick, 2012) whenever possible. Absorption cross sections of O₃, NO₂, H₂O and O₄ have also been included in the analysis. A Raman scattering cross section was generated by the Win-DOAS package (Fayt and Van Roozendael, 2001), calculated from Raman theory. Finally, the inverse of the reference spectrum was included as a pseudo cross section to account for stray light inside the spectrograph and the residual dark current of the detector. The air mass factor (AMF) used for the conversion of the NO₂ slant columns to vertical columns is the NDACC NO₂ standard AMF, available on the NDACC UV-Vis web page (http://ndacc-uvvis-wg.aeronomie.be/) and based on the Lambert et al. (1999) and (2000) climatology of the NO₂ profiles. This climatology consists of a Fourier harmonic decomposition of the UARS HALOE v19 and SPOT-4 POAM-III v2 NO₂ profile data. The cross sections and other parameters used in the analysis are shown in Table 1.

The estimated overall errors in the individual measurements are, on average, approximately 12 % (1–2 % fit analysis; < 2 % cross sections; 2 % reference spectrum; 2–3 % AMF; 2 % stratospheric temperature). For details, see Gil et al. (2008). Fit analysis, cross sections and reference spectra do not affect the trends. Potential long-term changes in the stratospheric temperature could have a minor effect on the effective cross sections, but no statistically significant changes in the stratospheric temperature have been observed during the data period. Only differences in the NO₂ profiles with respect to the AMF climatology used could have an effect of a few tenths of a percent.

The spectrometers are NDACC-qualified instruments (more information is available at http://www.ndsc.ncep.noaa.gov/data/) and have been successfully intercompared for NO₂ in ad hoc international exercises (Roscoe et al., 1999, 2010; Vandaele et al., 2005).

The DOAS technique at the zenith during twilight is slightly sensitive to clouds. Gaps in the data are mostly due to instrumental malfunctions. For monthly mean data, the rates of failures are 3.45, 0.40 and 0.79 % of the total dataset for Izaña, Ushuaia and Marambio, respectively.

3 Multiple regression and proxies

In the present work, a multiple linear regression model of the following form was used:

\[
Y(t) = a + \sum_{k=1}^{2} \left[ \beta_{2k-1} \sin \left( \frac{2\pi t k}{12} \right) + \beta_{2k} \cos \left( \frac{2\pi t k}{12} \right) \right] + \sum_{j=5}^{m+4} \beta_j X_j(t) + \varepsilon(t),
\]

where

- \( Y(t) \) is the NO₂ column at time \( t \),
- \( a \) is a constant,
- \( X_j \) is each of the explanatory functions,
- \( \beta_j \) is the coefficient of the corresponding explanatory function \( X_j \),
- \( t \) is the time since the start of the measurements, in months,
- \( \varepsilon \) is noise as a function of time \( t \), and
- \( m \) is the number of explanatory functions.

The bracketed terms represent the harmonic functions accounting for the annual and semi-annual waves, whereas the \( \beta X \) terms include all explanatory variables. In the first run, seven proxies that could potentially affect the NO₂ distribution are used (the trend, stratospheric aerosols, solar cycle, Quasi-Biennial Oscillation – QBO, stratospheric temperature, stratospheric circulation, and El Niño–Southern Oscillation – ENSO). Following Mäder et al. (2007), an iterative process was used to exclude proxies with confidence intervals below 90%. For details, see Mäder et al. (2007) and Knibbe et al. (2014). In this way, the degrees of freedom of the regression increase.

Autocorrelation affects the linear trend calculation by increasing the uncertainty. If autocorrelation of the data noise is not included, the standard deviation (SD) of the trend estimate will substantially underestimate the actual uncertainty. According to Weatherhead et al. (1998), the standard deviation of the trend per year to be used to describe the precision of the trend estimate can be approximated quite accurately by

\[
\sigma_\beta \approx \frac{\sigma_N}{\sqrt{1 + \phi}} \left( \frac{1}{n^{1/2}} \right)
\]

where \( \sigma_N \) is the standard deviation of the residuals (differences between the NO₂ data series and the modelled one), \( n \) is the length of the data series in years and \( n \) is the autocorrelation in the residual for time lag 1, defined as \( \text{Corr}(N_t, N_{t-1}) \). This formula has previously been used for trends in NO₂ (Van der A et al., 2006, 2008; Hendrick et al., 2012).
Stratospheric aerosols. Stratospheric aerosols (SA) affect the amount of available NO₃. An increase in the aerosol loading due to volcanic eruptions reduces the NO₃/NO₂ partitioning through the heterogeneous hydrolysis of N₂O₅ on the aerosol surfaces (Fuhey et al., 1993). The eruption of Mount Pinatubo in 1991 produced a reduction in the total NO₂ column of 19–34%, depending on the station, in the following years (Gruzdev, 2014). Therefore, SA have been included as a proxy in the analysis. The dataset is the monthly aerosol optical depth (AOD) for the NH at 0.55 μm, compiled at NASA’s Goddard Institute for Space Studies (GISS). The dataset ending in September 2012 has been extended in time to April 2014 by the optical spectograph and infrared imaging system (OSIRIS) data and to the end of 2014 by the white light optical particle counter (WOPC) data (Kremser et al., 2016). For the analysed period, SA proxy accounts for the short-range contribution of the volcanic aerosols to the NO₂ column which would, otherwise, affect the long-term trend.

Solar cycle. The solar radiation flux at 10.7 cm (2800 MHz) is an excellent indicator of solar activity. Unlike many solar indices, it can be easily and reliably measured on a day-to-day basis from the Earth’s surface in all types of weather. The 11-year solar cycle proxy is included to account for potential chemical changes due to variations in UV radiation. The data used are from the Penticton Radio Observatory in British Columbia.

QBO. The Quasi-Biennial Oscillation (QBO) affects the circulation in the lower stratosphere and hence the species distribution (Gray and Russell III, 1999). Recently, QBO signatures in the variability of the middle to upper stratosphere NO₂ have been detected (Liu et al., 2011). We employ a commonly used monthly index, built using the mean of the zonal winds averaged from three equatorial stations (Canton islands, Singapore and Gan/Maldives) compiled by the Berlin Free University for 50 and 10 hPa.

ENSO. The El Niño–Southern Oscillation (ENSO) has been found to influence the distribution of minor species in the tropical lower stratosphere up to 27 km (Randel et al., 2009). We have included as a proxy/predictor the multivariate ENSO Index (MEI) based on the six main observed variables over the tropical Pacific: the sea-level pressure (P), zonal (U) and meridional (V) components of the surface wind, sea surface temperature (S), surface air temperature (A), and total cloudiness fraction of the sky (C). Negative values of the MEI represent the cold ENSO phase (La Niña), while positive MEI values represent the warm ENSO phase (El Niño). For details, see Wolter and Timlim (2011). A time lag of 1 to 6 months has been tested since the middle stratosphere may take time to respond to tropical sea surface temperature anomalies (Sioris et al., 2014).

Stratospheric temperature. There is a growing consensus that the global temperature in the stratosphere shows a negative trend (Schwarzkopf and Ramaswamy, 2008); however, its magnitude is still under debate (Seidel et al., 2016). A recent study by Randel et al. (2016) based on satellite data shows a cooling trend of $-0.1$ to $-0.2$ K decade$^{-1}$ in the lower stratosphere and up to $-0.5$ to $0.6$ K decade$^{-1}$ in the middle stratosphere for the period 1979–2015, but most of this trend is due to the large decrease prior to 1995. After that date, no significant trend is observed (Seidel et al., 2016).

Temperature variations in the stratosphere modify the NO₂ concentration by changing the reaction rates. To account for the potential trends related to this effect, the stratospheric temperatures over the stations extracted from the Interim European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis (ERA-Interim) (Dee et al., 2011) have been used as a proxy. Temperature data are extracted from the 0.25° × 0.25° grid at levels corresponding to the height of the NO₂ maximum at each station, as obtained by the NO₂ harmonic climatology based on HALOE v19 and POAM-II data (Lambert et al., 1999), that is, 10 hPa for Izaña, 20 hPa for Ushuaia and 30 hPa for Marambio and Belgrano. We used the monthly mean of the average of the 00:00 and 12:00 UT values as a proxy.

Stratospheric circulation. Changes in BDC induce changes in the concentration of stratospheric species with tropospheric origins. Recent climate studies have found that BDC will intensify with the increase in greenhouse gases (Butchart, 2014). With a faster meridional circulation, N₂O of tropospheric origin has a shorter lifetime in the stratosphere, and, as a consequence, less N₂O would be oxidised to NO (Cook and Roscoe, 2009). To identify potential changes in the long-term NO₂ evolution associated with this effect, the eddy heat flux (EHF) ($\langle v' T' \rangle$) at 100 hPa, averaged over 45–75° S of the hemisphere, where the observational stations are located, has been included as a proxy in the multiple regression analysis. EHF is proportional to the vertical component of the Eliassen–Palm (EP) flux (Fusco and Salby, 1999; Salby and Callaghan, 2004), which has been found to have good correlation/anticorrelation with the extratropical/tropical O₃ (Randel et al., 2002; Weber et al., 2011). Data for the calculation of EHF were obtained from the ERA-Interim data, averaged for every month of the time series. The cumulative effects of the total NOₓ/NO₂ concentration were approximated by considering a delayed response in the EHF time series as follows (Bruner et al., 2006):

$$EHF(t) = EHF(t-1) e^{\frac{\Delta t}{\tau}} + EHF(t),$$

where EHF(t) is the data obtained from the ERA-Interim winds and temperatures and $\Delta t$ is the data time unit. For the Antarctic/Subantarctic stations $\tau$ was set to 12 for the months from April to September and was set to 3 for the rest of the year. For Izaña subtropical station it is set to 3 for the whole year.

In Table 2, the source of each proxy is summarised.
4 Results

4.1 General

The multiple regression fit is shown in Fig. 1 for Izaña, Ushuaia and Marambio. The model explains between 86 and 96% of the observed variance in all cases. The dominant pattern is, as expected, the seasonal wave, explaining between 57 and 85% of the variance, followed by the linear trend, explaining from 6 to 27% of the variance. The rest of the explanatory variables have modest contributions. The residuals and the trend were plotted together to search for common structures that could represent anomalies not captured by the model (Fig. 2). The morning and evening residuals look very similar, showing the non-random character of the departures of the model. Cross-correlation between the stations shows independent residuals (correlation coefficients: IZO/USH = +0.01, IZO/MAR = -0.08, and USH/MAR = +0.13). The trend is significant at 99%.

The results of the analysis show that the seasonal waves and trend are the major contributors to the variance, explaining 84.3/83.4, 91.0/92.2 and 89.2/94.8% of the variance for AM/PM at Izaña, Ushuaia and Marambio, respectively. As an example, Fig. 3 shows the individual contributions of the less relevant proxy terms (other than the seasonal and trend terms) for Izaña. They all maintain standard deviations below $5 \times 10^{13}$ molec cm$^{-2}$, representing less than 2% of the NO$_2$.
data series mean value \((2.45 \times 10^{15} \text{ molec cm}^{-2})\). The details of the trend analysis are summarised in Table 3.

To further explore the contributions of each proxy to the retrieved trend, a sensitivity test has been performed for data of the three stations. The results are shown in Fig. 4. Each data point represents the trend obtained when different proxies are excluded from the analysis. The first data point is the trend inferred considering all proxies from the monthly data series. The next six data points represent the trends when single proxies are excluded from the analysis, followed by the results obtained when excluding successively more proxies in order of their significance. Finally, the last data point represents the result of a simple linear regression. The results show that only stratospheric aerosols have a large impact at all three stations. Although the influence was restricted to the first years of the data (1993–1995), before the decay of the large sulfate aerosols load injected in the stratosphere following Pinatubo’s eruption in 1991, this influence does affect the trends of the complete series by 14 to 22%. Since the stratospheric aerosols reduce NO\(_2\) when removing the aerosol proxy, the trend increases with a positive trend (NH) and decreases when the trend is negative (SH). The EHF has no impact or significance and was removed from the final analysis. The impact of the stratospheric temperature is also very small, probably because the impact is accounted for by the seasonal waves. The rest have minor impacts (<5%).

Next, we explored the trend sensitivity to the data series length by reducing the period at both the starting and ending months. For this exercise, we chose the Izaña PM series. The results (Fig. 5) show that the trend remains essentially unchanged if the data series is shortened by up to 5 years at the start and up to 4 at the end, providing confidence in the stability of the trend. It can also be seen that the trend is largest during the last decade (2003–2014).

The decadal trends obtained from the mean AM and PM values for Izaña, Ushuaia, and Marambio are +8.7 ± 1.2, −8.7 ± 1.4, and −13.7 ± 2.2%, respectively. Most of the observed trends occurred in the last decade (after 2003–2006), as revealed by Fig. 2. At Izaña, the AM decadal trend is larger than the PM trend, +9.5 ± 1.2% vs. +7.9 ± 1.1%, respectively. McLinden et al. (2001), using a chemical transport model (CTM) to explain the NO\(_2\) trend observed at Lauder (Liley et al., 2000), found that the larger trends derived from the AM data are caused by decreasing O\(_3\), which, in turn, reduces the rate of NO\(_2\)+O\(_3\), allowing for more NO\(_2\) to be present the next morning. At Izaña, the different AM and PM trends cannot be explained by changes in O\(_3\) since a non-significant decadal trend of +0.5 ± 1.2% is obtained for the period of 1999–2012 by the FTIR instrument (Vigouroux et al., 2015). However, McLinden et al. (2001) predicted a decrease in the NO\(_2\) trend of approximately 1%, when exclusively considering the increasing halogens in the stratosphere between 1980 and 2000. Data from the past few decades show the opposite trend. Equivalent effective stratospheric chlorine (EESC) gas concentrations at the mid-latitudes have declined by 15% from their peak values in the year 2000. In particular, HCl, the main reservoir of inorganic chlorine, displays a negative decadal trend of −5.9 ± 1.5% between 1997 and 2012. The same declining rate is observed for bromine between 2000 and 2012 (WMO, 2014). The observed changes in both halogens should result in an increase in the NO\(_2\) trend. Moreover, the halogen decline would modify the daytime NO\(_3\) partition, since NO\(_2\) would increase during the illuminated hours and decrease in darkness (McLinden et al., 2001), creating a larger trend at dawn than at dusk, as is observed. In the SH, the AM and PM decadal trends are closer, −8.7 ± 1.4 and −8.7 ± 1.3% for Ushuaia, and −13.8 ± 2.1 and −13.6 ± 1.9% for Marambio, for AM and PM, respectively. At these stations, the decrease in halogens is probably compensated for by an increase in O\(_3\). Details of the trend analysis are summarised in Table 3.

At Belgrano, the trend has been obtained by averaging the decadal trends for the individual months, when data are available. Since DOAS requires SZAs close to 90°, only the February–April and August–November periods are suitable for measurements. For the sake of simplicity, we will refer to these periods as the summer and winter seasons, respectively. During the winter, the NO\(_2\) column reaches values close to zero, and its trends are non-significant. The mean summer decadal trend is −11.3 ± 4.0% (−10.9 ± 4.1 and −11.7 ± 4.0% for AM and PM, respectively). In Fig. 6, these results are summarised.

An alternative way of analysing the trends of the twilight data is to consider the evolution of the NO\(_2\) diurnal build-up...
Figure 4. Impact of the computed trends per month depending on the selected proxies. Case “All” means that all proxies are included. Labels indicate the proxy/es excluded from the analysis. The trend obtained in the final analysis is plotted as a reference (grey line). See the text for details.

Table 3. Summary of the trend analysis for the DOAS stations. In the lower part, the contribution of each explanatory variable to the total variance is given in %. The colours denote the significance (bold 99 %, italic 95 % and bold italic 90 %). “Not” means it has been excluded from the definite analysis.

99 %; 95 %; 90 %
and hours of the night, and can be expressed as a mean annual trend. In summary, all SH stations exhibit a photodissociation, which is dependent on temperature, O\(_3\) and W(z).

The DBU is essentially due to the N\(_2\)O\(_5\) photodissociation, which is dependent on temperature, O\(_3\) and the AM-to-PM ratio at a given height, and W(z) is a NO\(_2\) climatological profile acting as a weighting factor. R can be computed (Senne et al., 1996) from

\[
DBU = \frac{NO_{2,PM} - NO_{2,AM}}{24 - \Delta t}
\]

\[
= \frac{NO_{2,AM}}{24 - \Delta t} \left( 1 - \frac{\sum_{t=oa} W(z) R(z)}{\sum_{t=oa} W(z)} \right),
\]

where NO\(_{2,AM}\) and NO\(_{2,PM}\) are the columns at sunrise and sunset, respectively, and \(\Delta t\) is the monthly mean of the diurnal night hours. R is the AM-to-PM ratio at a given height, and W(z) is a NO\(_2\) climatological profile acting as a weighting factor. R can be computed (Senne et al., 1996) from

\[
R(z) = \frac{NO_{2,AM}(z)}{NO_{2,PM}(z)} = e^{-2K(z)O_3(z)\Delta t},
\]

where K is the NO\(_2\) + O\(_3\) reaction rate constant and O\(_3\)(z) is the ozone concentration at height z.

At Izaña, the DBU obtained from Eq. (4) using the O\(_3\) and temperature profiles from the local ozone sounding agree well with the observations (Fig. 7). The resulting decadal trend for the period is +5.5 ± 1.6 %, which provides a hint at the trends in the reservoirs. In the Subantarctic/Antarctic stations, the DBU displays negative decadal trends of −8.4 ± 1.8 and −13.8 ± 2.4 % for Ushuaia and Marambio, respectively. In Belgrano, the values are too low (winter) or the AM and PM data are too close (February) to obtain the DBU, except in March and April. The DBU decadal trends for these months are −13.0 ± 7.3 and −10.6 ± 2.9 %, which is probably not representative of the mean annual trend. In summary, all SH stations exhibit a negative decadal trend in their DBUs, ranging from −8 to −14 %, revealing either a reduction of N\(_2\)O\(_5\) in the past few years at the middle and high latitudes of the Southern Hemisphere or dynamically induced changes in the NO\(_2\) vertical distribution.

To investigate the variability of the NO\(_2\) trend with the season, the calculations were performed on a month-by-month basis. Even though the contributions of proxies other than seasonal waves are small (< 1 % in most cases), the same proxies and lags were applied in the multiple regression as in the previous cases. The results are shown in Fig. 8. The AM and PM trends were plotted separately for each station, along with their mean value. At Izaña, during the winter and spring, both trends agree well. From July to the end of the year, as the trend increases, there is also a progressive increase in the AM–PM difference that clearly exceeds the error bars. O\(_3\) trends in individual months (not shown) are too small and do not change much throughout the year. A seasonality in the decreasing halogen trend could be a possible explanation, but, for the moment, we have no satisfactory explanation for this behaviour. At Izaña, the monthly mean trends are largest in the autumn and beginning of the winter and are mainly forced by a faster increase in the AM trends. The annual excursion ranges from 4.4 % at its minimum in February to 13.1 % in December. The downward trends in the SH become more negative further south. At Ushuaia, the trend is less negative to values close to the annual minimum (−7 %), whereas in Marambio, the trend increases with respect to the previous months (−21 %). The time when the trends diverge coincides with the formation of the Antarctic Polar Vortex (APV), and

**Figure 5.** Dependency of the Izaña PM trend on the selected period. In the central point, the complete 1993–2014 time series is used. Each point to the left (orange circles) is the trend after reducing the time series by 1 year before 2014. Each point to the right (yellow circles) is the trend after reducing the time series by 1 year after 1993.

Figure 7. Diurnal NO$_2$ build-up in molec cm$^{-2}$ h$^{-1}$ for the four DOAS stations. (a)–(e): Observed DBU (black lines). Annual means (red lines). Linear trends (dotted lines). The computed DBU is plotted in (a) (blue line). (d) The Belgrano DBU for all available months (black stars). The months of March and April are highlighted with red circles and blue squares, respectively.

Figure 8. NO$_2$ decadal trends for the individual months at Izaña, Ushuaia, Marambio and Belgrano. Open circles and open squares represent the AM and PM data, respectively. Solid squares are the monthly means. The Belgrano trends are from the diurnal means. The shadowed area is the mean size of the area of the potential NAT (nitric acid trihydrated) PSCs (right scale).

this divergence extends for a period coincident with the coldest temperatures and polar stratospheric cloud (PSC) formation. In Fig. 8, the 2006–2016 mean area covered by temperatures low enough for PSC formation, as obtained by the Climate Prediction Center (CPC) (http://www.cpc.ncep.noaa.gov/products/stratosphere/polar/polar.shtml), is shown in grey. In September, the absolute maximum of the negative trends is reached at both stations as a result of an increase in the number of days that the stations were inside the APV. We will come back to this point later.

During the autumn and winter, there is meridional transport towards the pole. Once the Antarctic vortex is established, O$_3$ and NO$_2$ transported from lower latitudes accumulate outside the vortex, since the vortex edge acts as a barrier for mass exchange. Marambio is generally at the edge of the vortex, whereas Ushuaia remains outside, with very few exceptions. The observed behaviour could be explained by a positive trend in the size of the vortex area, such that Marambio remains inside the vortex longer, thus reducing its NO$_2$ column year by year. Conversely, larger NO$_2$ masses transported from lower latitudes would accumulate above Ushuaia, somehow compensating for the negative trend. Alternatively, the same effect could be caused
by a drift of the average vortex position towards the Atlantic/Argentinean sector. The drifting of the APV during the spring has been studied over the past decade (Hassler et al., 2011; Grytsai et al., 2017) using both observations and models. The results show longitudinal displacements of the APV across the years. In particular, the minimum of the planetary wavenumber 1, centred at latitudes of approximately 65°S, has shifted westward since 2003, thus increasing the time of the stations in the Argentinean sector under the influence of the PVA. To confirm this effect over Ushuaia and Marambio, the NO₂ representative potential temperature level of 530 K between days 150 and 330 (May through to November) has been used to calculate the position of the station with respect to the vortex according to the widely accepted Nash et al. criteria (Nash et al., 1996), based essentially on finding the maximum PV gradient at equivalent latitudes to define the vortex edge. ERA-Interim data were used for this purpose. The results show an increasing number of days inside the vortex in both Ushuaia and Marambio in previous years (Fig. 9). To test whether the impact of the vortex position drifting is the main cause of the wavy structure in the trend observed in the Ushuaia winter (small trends in July–August, large ones in September–October; see Fig. 8), we have repeated the monthly trend analysis, excluding the days when the station was inside the vortex. Results show that while, as expected, negative trends are reduced, the magnitude is not enough to justify the observed trends. In fact, the changes are only a few tenths of a percent, probably due to the fact that the days inside the vortex at Ushuaia, while increasing along time, are still very small compared with the total number of days. In summary, when only extra-vortex data are used, the winter wavy structure remains, providing evidence that the evolution of the seasonal NO₂ trend is dominated by the mid-latitude dynamics along the year.

The trends at Belgrano in the summer are lower than those at Marambio, with values close to those at Ushuaia. The winter data are not significant. The NO₂ concentration in the stratosphere during these months is very low and very dependent on the time of the last warming, which is highly variable from year to year.

4.2 The subtropical case: comparisons with other observations

DOAS trends at Izaña have been compared with the ground-based NDACC FTIR data located in the same station and with three satellite instruments: nadir SCIAMACHY (SCanining Imaging Absorption spectroMeter for Atmospheric CHartographY) and OMI (Ozone Monitoring Instrument), both DOAS spectrometers, and the limb sounding FTIR MIPAS (Michelson Interferometer for Passive Atmospheric Sounding). The SCIAMACHY stratospheric data are produced by the IUP-Bremen. The data used here are the improved version V3.0 released in 2016.
The MIPAS NO\textsubscript{2} profiles are from IMK/IAA data version v5h NO\textsubscript{2} 20/v5r NO\textsubscript{2} 220 at the station’s location converted to VCD. Only the daytime data (10 AM overpasses) were considered. The MIPAS data have been combined with the DOAS averaging kernels to make them comparable. The basic instruments are shown in Table 4. Further details can be found on the corresponding web pages. Figure 10 shows the annual mean values (upper panel) obtained from the monthly means (lower panel) to avoid potential biases due to a non-uniform distribution of data available across the year. This is particularly important for the ground-based FTIR data, since there are many more daily measurements during the summer months, when NO\textsubscript{2} is at maximum, than in other months. Only in the few cases when the monthly data were not available were the corresponding climatological values used. No photochemical correction has been applied to the satellite data to refer them to the same SZA because the purpose is to compare the NO\textsubscript{2} column trends. The differences between the instruments for the monthly means are within 5% and exhibit similar seasonalities (Fig. 10, lower panel). There are multiple causes affecting the magnitude of the measured column, namely, the hour of the measurements, field of view, and vertical sensitivity (Piters et al., 2011; Robles-Gonzalez et al., 2016); however, these factors should not affect the observed trends. Table 5 displays the results of the trends from the regression model using the monthly data. There is a large scatter in the trends. The MIPAS decadal trend is $+5.0 \pm 3.5\%$, close to that of FTIR ($+3.6 \pm 2.7\%$). SCIAMACHY provides a low trend but is statistically non-significant. OMI shows a decadal trend of $+7.5 \pm 2.2\%$, not far from that obtained from DOAS but for the 2002–2014 period. MIPAS and OMI are significant at the 90% confidence level. In summary, at present, there is no agreement between the instruments and the actual trend over Izaña. To further complicate the interpretation, McLinden et al. (2001), using a 3-D CMT model, found that the trend can be highly dependent on the time of day of the measurement. For the case shown in their paper, i.e. with decreasing O\textsubscript{3} and increasing halogens, there is almost a factor of 2 between the maximum trend at sunrise and the trend minimum at sunset. In the late morning and around noon, when the satellites and FTIR measurements are taken, the trend is much lower than that at SZA = 90° AM, when the DOAS takes its measurement. Therefore, unless careful analyses of the CTM models are carried out for the exact periods of the measurements, the trend intercomparisons of a set of measurements obtained at different times of day has been found to be of little use for the confirmation of the DOAS trend. There is little doubt, however, of the sign of the trends since all instruments show a positive trend.

4.3 Discussion of the hemispheric asymmetry

The opposite sign in the NO\textsubscript{2} trends observed at the NH and SH stations shows that the NO\textsubscript{2} distribution in the stratosphere does not directly reflect the increasing N\textsubscript{2}O in the atmosphere, at least when individual stations are analysed. Stratospheric temperatures from the ECMWF ERA-Interim data above the NH and SH stations show no statistically significant trends during the period of observation. The EHF has been used as a proxy for the meridional transport as a possible explanatory variable for the trends observed in the analysis, but no significant correlation has been obtained. Eckert et al. (2014) found a similar hemispherically asymmetric pattern when analysing the global ozone trends from MIPAS. Negative trends were found in the northern lower stratosphere, whereas positive values were observed in the Southern Hemisphere. These authors suggested a meridional displacement of the subtropical barriers as the cause of the hemispheric asymmetry, since they could mimic the observed trends by shifting the subtropical mixing barriers to the south by 5° at altitudes below 30 km, although no explanation was provided for the displacement beyond what is possible due to low-frequency natural variations. Previously, Stiller et al. (2012) computed the age of stratospheric air (AoA) in the stratosphere using MIPAS sulfur hexafluoride (SF\textsubscript{6}) measurements, finding a positive trend in the Northern Hemisphere, centred at 20 km from 20 to 60° N, and a negative trend in the tropics and the Southern Hemisphere. In particular, the increasing AoA was observed at heights from the tropopause to the upper limit of MIPAS (38 km). The MIPAS AoA has been reassessed (Haenel et al., 2015), but the hemispheric asymmetry remains. Total positive reactive NO\textsubscript{2} trends in the Northern Hemisphere and the negative
trends in the Southern Hemispheric asymmetry in stratospheric NO$_2$ trends (≈ 25 km) have been reported by Funke et al. (2015), using the MIPAS data from the period 2002–2012. A more detailed meridional structure of the NO$_2$ trends was obtained by Burrows et al. (2016) by analysing the SCIAMACHY NO$_2$ limb measurements in 2003–2011. They find a well-defined region with positive/negative trends extending from the Equator to the high latitudes in the Northern Hemispheric aspheric circulation pattern between the potential temperature levels of 500 and 800 K. Additionally, Garfinkel et al. (2017), using the GEOSCCM model, also found an increase in the Southern Hemispheric AO for the period after 1992 when including the stratospheric aerosols and ODS evolution in the simulation. The positive trend peaks between 20 and 30° N and extends from 20 to 40 km.

In summary, previous works exhibit discrepancies in the heights where the stratospheric trends peak (AOA, ozone and NO$_2$) but agree on the existence of a change in sign between hemispheres in the stratospheric trend. Although the search for an explanation of the observed hemispheric asymmetry patterns is outside the scope of this paper, there is growing evidence based on observational analysis and modelling of a redistribution of tracers in the stratosphere in the past few decades. The results presented here provide an additional confirmation of the changes in the dynamics of the lower/middle stratosphere based on data from an independent source.

5 Conclusions

Long-term datasets from the DOAS spectrometers located at remote stations (Izana, 28° N, Ushuaia, 55° S, Marambio, 64° S, and Belgrano, 78° S) have been used to calculate the trends in the NO$_2$ stratospheric column over the 1993/94–2014 period. Seasonal cycles, stratospheric aerosols, solar cycles, ENSO, QBO, stratospheric temperature, and eddy heat flux were included as explanatory variables. The results show a positive mean NO$_2$ decadal trend of 8.7 ± 1.2 % over the past 23 years at the northern subtropical station at Izana, surpassing the expected 2.5 % increase due to the positive N$_2$O trend. The observed trend is larger at dawn (9.5 ± 1.2 %) than at dusk (7.9 ± 1.1 %). The attempt to compare other available databases does not provide confirmation of the observed DOAS trend, due to either the shorter time series, larger uncertainties, or different diurnal sampling. The same analysis applied to the Antarctic/Subantarctic stations
displays the opposite trends. The NO$_2$ stratospheric column has been found to decrease at a mean rate of $-8.7 \pm 1.4$ and $-13.8 \pm 2.2$ % decade$^{-1}$ for Ushuaia and Marambio, respectively. Most of the observed trends occurred in the last decade (after 2003–2006). Belgrano also displays a negative trend of $-11.3 \pm 4.0$ % for the summer/autumn season, which is the only period that is statistically significant. The trend in the NO$_2$ diurnal build-up (DBU) rate is essentially due to N$_2$O$_5$ photolysis and is $+5.5 \pm 1.6$ % at Izaña, $-8.4 \pm 1.8$ % at Ushuaia and $-13.8 \pm 2.4$ % at Marambio, providing a hint about the NO$_3$ trend.

The analysis of individual months shows that the trend is largely dependent on the season. The decadal trends’ annual excursion at Izaña ranges from $4.4 \pm 1.8$ % at its minimum in February to $13.8 \pm 2.8$ % in December. The Southern Hemisphere station trends are strongly influenced by the Antarctic polar vortex. The negative trend at Marambio increases in mid-winter ($-21$ %), whereas at Ushuaia, the decadal negative trend is reduced to values close to its annual minimum during the same time ($-7$ %). The largest trend is observed in September. Analysis excluding the APV air data indicates that the shift of the APV toward the South American sector during the past decades.

The results presented here provide an additional confirmation of the changes in the lower/middle stratosphere dynamics based on data from an independent source and provide 30 further observational evidence of the recent findings on the hemispheric asymmetry in stratospheric NO$_2$ and the age of air during the past decades.

Data availability. Izaña DOAS data are available via ftp at the NDACC database ftp://ftp.cpc.ncep.noaa.gov/ndacc/station/izana. Belgrano, Marambio and Ushuaia DOAS data are available from the corresponding authors upon request.

Competing interests. The authors declare that they have no conflict of interest.

Special issue statement. This article is part of the special issue “Twenty-five years of operations of the Network for the Detection of Atmospheric Composition Change (NDACC) (AMT/ACP/ESSD inter-journal SI)”. It is not associated with a conference.

Acknowledgements. The authors want to acknowledge the station operations teams, who were particularly valuable at the remote locations. The FTIR data were provided by the Izaña-FTIR team at the Karlsruhe Institute of Technology (Thomas Blumenstock). Long-term measurements were made possible thanks to the funding provided by EU Framework programme NORS (FP7/2007-2013 under grant agreement no. 284421) and Spanish R+D Plan projects AMISOC (CGL2011-24891), AVATAR (CGL2014-55230-R), VIOLIN (CGL2010-20353) and HELADO (CTM2013-41311-P). The trend analysis was programmed with the GNU OCTAVE version 4.2.0 free software.
