Abstract. The effects of atmospheric aerosol particles on the Earth’s climate mainly depend on their optical, microphysical and chemical properties, which modify the Earth’s radiative budget. The aerosol radiative effects can be divided into direct and semi-direct effects, produced by the aerosol–radiation interactions (ARIs), and indirect effects, produced by aerosol–cloud interactions (ACIs). In this sense the objective of this work is to assess whether the inclusion of aerosol radiative feedbacks in the online coupled WRF-Chem model improves the modelling outputs over the Iberian Peninsula (IP) and surrounding water areas. For this purpose, the methodology is based on the evaluation of modelled aerosol optical properties under different simulation scenarios. The evaluated data come from two WRF-Chem simulations for the IP differing in the inclusion/no-inclusion of ARIs and ACIs (RF/NRF simulations). The case studies cover two episodes with different aerosol types over the IP in 2010, namely a Saharan dust outbreak and a forest fire episode. The evaluation uses observational data from AERONET (Aerosol Robotic Network) stations and MODIS (Moderate Resolution Imaging Spectroradiometer) sensor, including aerosol optical depth (AOD) and Ångström exponent (AE). Experimental data of aerosol vertical distribution from the EARLINET (European Aerosol Research Lidar Network) Granada station are used for checking the models. The results indicate that for the spatial distribution the best-represented variable is AOD and the largest improvements when including the aerosol radiative feedbacks are found for the vertical distribution. In the case of the dust outbreak, a slight improvement (worsening) is produced over the areas with medium (high/low) levels of AOD (−9%/+12% of improvement) when including the aerosol radiative feedbacks. For the wildfire episode, improvements of AOD representation (up to 11%) over areas further away from emission sources are estimated, which compensates for the computational effort of including aerosol feedbacks in the simulations. No clear improvement is observed for the AE representation, the variability of which is largely underpredicted by both simulations.

1 Introduction

Nowadays, it is widely recognized that aerosol particles exert a substantial influence on the Earth’s climate, changing the radiative budget (Charlson et al., 1992; Hansen et al., 1997; Ramanathan and Feng, 2009; Boucher et al., 2013, IPCC, 2013, among many others). The principal mechanisms by which aerosols cause these changes are (1) scattering and absorption of solar and terrestrial radiation (aerosol–radiation interactions, ARIs) (e.g. Ruckstuhl et al., 2008) and (2) modification of clouds and precipitation, thereby affecting both radiation and hydrology, or increasing the reflectivity of clouds (aerosol–cloud interactions, ACIs) (e.g.
Twomey, 1974, 1991; Albrecht, 1989). In the first case, light scattering by aerosol particles such as sea salt increases the solar radiation reflected by the planet, producing a cooling influence. Light-absorbing aerosols such as black carbon, which are a component of biomass burning, exert a warming influence (e.g. Jacobson, 2001). These radiative influences are quantified as forcings (in W m\(^{-2}\)), defined as the perturbation to the energy balance of the Earth–atmosphere system. A warming influence is denoted a positive forcing, and a cooling influence, a negative forcing (IPCC, 2013).

Generally, modelling tools and observations indicate that anthropogenic aerosols have had a cooling influence on Earth since preindustrial times, with a total ARI+ACI medium-confidence radiative forcing (excluding the effect of absorbing aerosol on snow and ice) of \(-0.9 \text{ to } -0.1\) W m\(^{-2}\) (Boucher et al., 2013). The uncertainty quantification of these aerosol effects on the Earth’s radiative budget is much higher than for any other climate-forcing agent (IPCC, 2013). This happens because the physical, chemical and optical aerosol properties are highly variable on scales of space and time due to the short-lived aerosol particles and non-uniform emissions (Forster et al., 2007).

In order to reduce this uncertainty, the use of models is one of the most powerful ways of understanding the different processes affecting the climate system. As aerosols may strongly drive the Earth’s climate on global and regional scales, fully coupled meteorology–climate and chemistry models allow for accounting for the climate–chemistry–aerosol–cloud–radiation feedback mechanisms between simulated aerosol concentrations and meteorological variables. It is also a promising way to go for future atmospheric simulation systems, leading to a new generation of models for improved meteorological, environmental and chemical weather forecasting (Baklanov et al., 2014).

Europe may be one of the most climatically sensitive world regions (Giorgi, 2006). Within the target domain, the role of aerosol particles may then be even more crucial over such regions as the Mediterranean basin, a crossroad that fuels the mixing of particles from different sources (Papadimas et al., 2012). The Iberian Peninsula (IP), a good example within the Mediterranean basin, can be affected by high aerosols concentration of different aerosol types. Due to its closeness to the Sahara, the IP is frequently affected by dust outbreaks with large aerosol loads that modulate the aerosol climatology in different areas of this region, especially in southern Spain (e.g. Toledano et al., 2007; Guerrero-Rascado et al., 2008, 2009; Córdoba-Jabonero et al., 2011; Antón et al., 2012; Pereira et al., 2014) and Portugal (e.g. Wagner et al., 2009; Preißler et al., 2011). On the other hand, the Mediterranean climate, with high summer temperatures and dry soil–air conditions, encourages forest fire episodes over this region (Alados-Arboledas et al., 2010). Both types of emissions have major contributions to particle concentration in the atmosphere, particularly in the warmer season (Elías et al., 2006).

There are a large number of studies assessing the aerosol feedback effects over the IP using different remote-sensing measurement methods and devices such as sun photometers (Lyamani et al., 2005, 2006; Toledano et al., 2007; Cachorro et al., 2008; Obregón et al., 2012), nephelometers (Pereira et al., 2008, 2011), lidars (Guerrero-Rascado et al., 2008) or a combination of these (Elías et al., 2006; Córdoba-Jabonero et al., 2011). Other studies using these instruments share the satellite measurements when this assessment is carried out (Cachorro et al., 2006; Guerrero-Rascado et al., 2009). Furthermore, there are studies that use these different measurements to estimate the aerosol radiative forcing over some regions (Santos et al., 2008; Guerrero-Rascado et al., 2009; Valenzuela et al., 2012) or over the whole of the IP using a radiative transfer model (Mateos et al., 2014). On the other hand, a number of studies (e.g. Pérè et al., 2010; de Meij et al., 2012; Curci et al., 2014, among others) take a more regional approach. However, no modelling studies of the aerosol radiative effects have ever been carried out for the IP.

According to Randall et al. (2007), the responses of the climate system to aerosols and their effects on the radiative budget of the Earth are the most uncertain climate feedbacks. Therefore, the objectives of this work are (i) to assess whether the inclusion of aerosol radiative feedbacks in the online coupled WRF-Chem model improves the modelling outputs of aerosol optical properties (aerosol optical depth, AOD, and Ångström exponent, AE) over the IP and surrounding water areas (seas and ocean) and (ii) to evaluate the representation of aerosol optical properties by this model over the target domain.

2 Methodology

In this paper we evaluate the AOD and AE outputs of different simulations carried out by the WRF-Chem model (Grell et al., 2005) by using observational data provided by several instruments: two ground-based data networks (AERONET and EARLINET) and a sensor on board a satellite (MODIS). The results of the evaluation of the simulations presented here, concerning particulate matter concentrations, can be found in Im et al. (2015). Therefore, in this contribution we will focus on the evaluation of aerosol properties. Two different set-ups of the model have been considered, with or without aerosol radiative feedbacks in the simulation. According to Boucher et al. (2013), the inclusion of these feedbacks involves a change in the internal energy flows to the Earth’s system, affecting cloud cover or other components of the climate system such as aerosol particles, thereby altering the global energy budget indirectly.

The evaluation has been performed by using classical statistics according to Willmott et al. (1985), Weil et al. (1992) and Willmott and Matsuura (2005). The individ-
ual model prediction error or bias ($e_i$), the mean bias error (MBE), mean absolute error (MAE) and the correlation coefficient ($r$) have been calculated. All data need to be preprocessed and bilinearly interpolated to a common working grid. This has a resolution of 0.2° and covers between 35 and 47° north and −15 and 5° east. The grid size consists of 6000 cells and the grid type is a regular lon–lat grid. After the interpolation, modelled data are evaluated against MODIS. The data to be compared with AERONET and EARLINET are extracted from the model cell covering the corresponding station coordinates (Fig. 1) following a nearest-neighbour approach.

First, in order to evaluate whether the inclusion of aerosol radiative feedbacks in the online coupled WRF-Chem model produces significant changes on the studied variables (or changes are just mere signal noise), a surrogate variable, associated to the significance level of the changes modelled (S.L.), is defined (Eq. 1). Therefore, high values of S.L. indicate whether the changes between simulations with (and without) aerosol radiative feedbacks are noticeable with respect to the variability of the signal or not and, therefore, their significance is as follows:

$$S.L. = \frac{1}{n} \sum_{i=1}^{n} \left| \frac{x_{\text{NRF}} - x_{\text{RF}}}{\sigma_{\text{NRF}}} \right| \times 100,$$

where S.L. is the significance level, $x_i$ is the value of the studied variable and $\sigma^2_{\text{NRF}}$ is the associated variance for the case not taking into account any aerosol radiative feedbacks (no radiative feedbacks, NRFs). Moreover, NRFs represent the base case and RF is the aerosol radiative feedbacks simulation that includes the ARI+ACI.

Second, to evaluate whether the inclusion of the aerosol radiative feedbacks in the simulations leads to an improvement of the error of the model, the variable improvement of the MAE is used (Eq. 2):

$$\text{Improvement of MAE} = \frac{1}{n} \sum_{i=1}^{n} |e_i|_{\text{NRF}} - \frac{1}{n} \sum_{i=1}^{n} |e_i|_{\text{RF}}. \tag{2}$$

where $|e_i|$ is the absolute error of the simulations.

Finally, to estimate whether the inclusion of the aerosol radiative feedbacks in the simulations produces an improvement in the vertical distribution of aerosols, the normalized improvement of the MAE has been calculated (Eq. 3):

$$\text{Nor. Improv. of MAE}(\%) = \frac{1}{n} \left( \frac{\sum_{i=1}^{n} |e_i|_{\text{NRF}} - \sum_{i=1}^{n} |e_i|_{\text{RF}}}{\sum_{i=1}^{n} |e_i|_{\text{NRF}}} \right) \times 100. \tag{3}$$

2.1 Modelling data: WRF-Chem

The evaluated data come from regional air-quality–climate simulations performed using the WRF-Chem online coupled meteorology and chemistry model (Grell et al., 2005), version 3.4.1, under the umbrella of the EuMetChem COST Action ES1004. A detailed description of the simulations can be found in Forkel et al. (2015).

A brief description of the modelling methodology taken from the aforementioned work is described below. The following physics options were applied for both simulations, with (or without) aerosol radiative feedbacks: the Rapid Radiative Transfer Model for Global Climate Models (RRTMG) longwave and shortwave radiation scheme; the Yonsei University (YSU) PBL scheme, the Noah land-surface model, the Lin microphysics scheme and the updated version of the Grell–Devenyi scheme with radiative feedbacks. Further description of the physics can be found in Grell et al. (2005). According to the chemistry options, the following were applied: the Modal Aerosol Dynamics model for Europe with the Secondary Organic Aerosol Model (MADE/SORGAM) aerosol scheme, the Regional Acid Deposition Model version 2 (RADM2) gas phase mechanism and the Fast-J photolysis scheme.

For all simulations discussed in this paper the native modelling grid spacing is 23 km (270 by 225 grid cells, Lambert conformal conic projection with the centre at 50° N and 12° E). The modelling domain covers Europe and a portion of northern Africa as well as large areas affected by the Russian forest fires. However, because the scope of the paper is the IP, only data for a domain covering the IP and the surrounding seas and ocean have been used (Fig. 2). In the vertical direction, the atmosphere up 50 hPa is resolved into 33 layers with a higher resolution close to the surface.

Initial and boundary conditions for the meteorological variables were obtained from 3-hourly data with 0.25° resolution (analysis at 00:00 and 12:00 UTC and respective forecasts 3/6/9 h) from the ECMWF operational archive. Three-hourly chemistry boundary conditions for the main trace gases and particulate matter concentrations were available from the ECMWF IFS-MOZART model run.
from the MACC-II project (Monitoring Atmospheric Composition and Climate Interim Implementation, Inness et al., 2013) 1.125° spatial resolution. Anthropogenic emissions for the EU domain provided by the TNO (Netherlands Organization for Applied Scientific Research) from a recent update of the TNO MACC emissions inventory (http://www.gmes-atmosphere.eu/; Pouliot et al., 2012, 2014; Kuenen et al., 2014) were applied.

Biomass burning emission data have been calculated from global fire emission data, which have been supplied by the Integrated Monitoring and Modelling System for wildland fires (IS4FIRES) project (Sofiev et al., 2009) with 0.1° × 0.1° spatial resolution. Day and night vertical injection profiles were also provided. WRF-Chem emission species have been calculated by speciation following Andreae and Merlet (2001) and Wiedinmyer et al. (2011). However, no heat release due to the fires was taken into account.

Biogenic emissions are based on the Model of Emissions of Gases and Aerosols from Nature (MEGAN) model (Guenter et al., 2006). MEGAN is online, coupled with WRF-Chem and makes use of simulated temperature and solar radiation. Moreover, WRF-Chem predicts online dust emission as a function of the land usage information and the simulated meteorological fields. In this work and following Shaw et al. (2008), dust emission flux (G) depends on an empirical proportionality constant estimated from region-specific data (C), the vegetation mask accounting for vegetation type (α), the friction velocity (u∗), the threshold friction velocity below which dust emission does not occur (u∗th = 20 cm s⁻¹) following Shaw et al., 2008) and the soil wetness factor accounting for soil moisture (f_w).

\[
G = \alpha C u^4 \left(1 - \frac{f_w u^*}{u^*_{th}}\right)
\]  

The most important feature to bear in mind for this work is the aerosol module. This aerosol module is based on the modal aerosol MADE (Ackermann et al., 1998), which is a modification of the Regional Particulate Model (Binkowski and Shankar, 1995). Here aerosol particles are represented by three log-normal size distributions, corresponding to an Aitken mode (nucleation mode 0.1 µm diameter), an accumulation mode (0.1–2 µm) and a coarse mode (> 2 µm) (Forkel et al., 2012). Secondary organic aerosols (SOAs) have been incorporated into MADE in the SORGAM (Secondary Organic Aerosol Model) module (Schell et al., 2001).

Aerosol chemical properties and sizes are used to determine aerosol optical properties as a function of wavelength using the method outlined in Fast et al. (2006) and Barnard et al. (2010). In brief, each chemical constituent of the aerosol is associated with a complex index of refraction. The overall refractive index for a given size bin is determined by volume averaging, with Mie theory and summation over all size bins used to determine composite aerosol optical properties. Wet particle diameters are used in the calculations (Chapman et al., 2009).
The microphysical module, consisting of the Lin scheme based on Lin et al. (1983) and Rutledge and Hobbs (1984), is a single-moment scheme including some modifications, as saturation adjustment following Tao et al. (1989) and ice sedimentation, which is related to the sedimentation of small ice crystals (Mitchell et al., 2008). It includes six classes of hydrometeors: water vapour, cloud water, rain, cloud ice, snow and graupel (Baró et al., 2015). The WRF-Chem model allows us to transform the single moment scheme of the Lin microphysics scheme into a double moment scheme. This implementation is described in Chapman et al. (2009). Following Ghan et al. (1997), a prognostic treatment of cloud droplet number was added, which treats water vapour and cloud water, rain, cloud ice, snow and graupel. The autoconversion of cloud droplets to rain droplets depends on droplet number and follows Liu et al. (2005). Droplet-number nucleation and (complete) evaporation rates correspond to the aerosol activation and resuspension rates. Ice nuclei based on predicted particulates are not treated. However, ice clouds are included via the prescribed ice nuclei distribution following the Lin scheme (Baró et al., 2015).

Finally, the effect of aerosols on incoming solar radiation within WRF-Chem is determined by transferring relevant parameters to the shortwave radiation scheme, representing radiative feedbacks due to aerosol–cloud interactions. A limitation of WRF-Chem in the treatment of aerosol–cloud interactions is that these couplings are not computed in convective clouds simulated by the cumulus parameterization (Chapman et al., 2009; Yang et al., 2011; Archer-Nicholls et al., 2016).

Although the modelling domain covers all Europe, for the purpose of this work, data from the IP and surrounding areas with a resolution of 0.2° have been extracted for two important aerosol episodes in 2010. One of these episodes consists of a Saharan dust outbreak (from 28 June to 12 July) and a forest fire episode (from 25 July to 7 August). These episodes are selected because they represent two situations with a high load of atmospheric aerosol particles, which cause the radiative budget to be strongly affected. No volcanic emissions were considered in spite of the Eyjafjallajökull eruption in spring 2010. However, the volcanic plume only reached the whole of the IP in May 2010 (Sicard et al., 2012; Navas-Guzmán et al., 2013), so it is outside the scope of this case study.

The simulations are run for two different configurations differing in the inclusion/no-inclusion of aerosol radiative feedbacks (ARI+ACI). The base case, or NRF simulation, does not take into account any aerosol feedbacks and the RF simulation adds the ARIs and ACIs to the previous modelling set-up. At this point, it should be mentioned that the use of the ECMWF operational archive for meteorological initial and boundary conditions can result in some of the aerosol feedback being taken into account in the base case (NRF).
because of the model assimilation of meteorological observations by the ECMWF.

2.2 Observational data

2.2.1 Moderate Resolution Image Spectrometer (MODIS)

The satellite data chosen to evaluate the WRF-Chem simulations come from MODIS (Levy et al., 2005) Level-2 Atmospheric Aerosol Product (MXD04_L2), collection or version 6 (C6) (Levy et al., 2013). The MODIS Aerosol Products monitor the ambient aerosol optical thickness over the oceans globally and over a portion of the continents. Daily Level 2 data have a spatial resolution of a 10 × 10 km. Two MODIS Aerosol data product files have been selected: MOD04_L2, containing data collected from the Terra platform, and MYD04_L2, containing data collected from the Aqua platform. In this case, the MXD04_L2 provides full global coverage of aerosol properties from the dark target (DT) aerosol retrieval algorithm, which is applied over ocean and dark land (e.g. vegetation) (Levy et al., 2013).

The variables used from MODIS are aerosol optical depth (AOD) and Ångström exponent (AE).

The AOD is measured at a wavelength of 550 nm (AOD550) for both ocean (best) and land (corrected) with the highest-quality data (quality assurance confidence = 3). The valid range of data is −0.05 to 5.0; that means a permission of small negative AOD values in order to avoid an arbitrary negative bias at the low AOD550 end in long-term statistics. This is because MODIS does not have sensitivity over land to retrieve aerosol to better than ±0.05 ± 15% under very clean conditions. Negative values of AOD550 have been considered to be zero in this study. Over ocean the estimated error is −0.02 and +0.04 ± 10% (Levy et al., 2013).

AE for wavelengths between 550 and 860 nm (AE550/860) over the ocean has a valid range of −1.0 to 5.0. In collection 6, the preliminary estimated error for AE550/860 is 0.45; pixels with an AOD550 > 0.2 are expected to have a more accurate AE550/860 representation (Levy et al., 2013).

2.2.2 Aerosol Robotic Network (AERONET)

The Aerosol Robotic Network (AERONET) collaboration (Holben et al., 1998) provides globally distributed observations of spectral AOD, inversion products and precipitable water in diverse aerosol regimes. The highest-quality data can be found in Version 2, Level 2.0 (cloud screened and quality assured) data products.

The data used from AERONET in this work come from level 2.0 of AOD at different wavelengths (AOD440, AOD675, AOD870 and AOD1020) and AE (AE440/870) from stations covering the IP for the episodes studied (Fig. 1). Typically the total uncertainty for AOD data under cloud-free conditions is
2.2.3 European Aerosol Research Lidar Network (EARLINET)

EARLINET (Pappalardo et al., 2014) is the first aerosol lidar network, established in 2000, with the main goal of providing a comprehensive, quantitative and statistically significant database for the aerosol distribution on a continental scale. EARLINET data include particle backscatter and extinction coefficient profiles at 355, 532 and 1064 nm. EARLINET data used include backscatter profiles (BSCAT) at 355 and 532 nm (for the dates and times selected, no information is available at 1064 nm). The only station with available data for the case studies in the IP during the year 2010 is Granada and, therefore, it is the only station included in this study.

3 Results and discussion

3.1 Significance level of simulated changes

First, to assess the effect of the inclusion of aerosol radiative feedbacks in the online coupled WRF-Chem model on the studied variables, the significance study described in Sect. 2 has been carried out. During the dust episode (Fig. 2), the inclusion of aerosol radiative feedbacks produces differences with a significance level (defined as the ratio for the NRF-RF differences and the associated variance for the case not taking into account any aerosol radiative feedbacks) for AOD\textsubscript{550} higher than 60\% over the south-western IP. The rest of the domain presents S.L. ratios > 100\% in spite of the high AOD\textsubscript{550} variance values (above 0.05). In the case of AE\textsubscript{440/870}, the entire domain shows significance levels higher than 100\%.

The inclusion of aerosol radiative feedbacks during the simulated fire episode (Fig. 3) produces differences with a S.L. > 100\% for AOD\textsubscript{550} over most of the domain. Over
the area of fire particle emissions, S.L. ranges between 50 and 100 % due to the higher absolute changes (>0.2) than variance values (>0.05). Similarly, for the dust episode the AE440/870 over the entire domain shows significance levels > 100 %.

Hence, over most of the domain, the changes or differences due to the inclusion of aerosol radiative feedbacks have a high S.L., usually higher than 100 %, and therefore the changes modelled are significant with respect to the variability of the studied variables. We can then state that the changes discussed below are caused by the inclusion of the aerosol radiative feedbacks in our simulations and not merely by signal noise.

3.2 Model output vs. Terra-MODIS data

The results of the comparison between model outputs with MODIS data from the Terra platform are shown in Figs. 4–7. The results from the Aqua platform are similar to Terra, and are therefore not shown here (but included in the Supplement). Figure 4a shows the mean values of AOD550 from MODIS for the dust outbreak. In this episode, high levels (above 0.4) over the south and the east of the domain are found, due to the shape of the dust outbreak. On the other hand, for the fire episode (Fig. 5a), the highest levels of MODIS AOD550 (>0.25) are shown over the north of Portugal due to the presence of black carbon from wildfires, and over the south of the domain, where a dust intrusion occurred at the end of this episode (>0.3).

For AOD550 over the entire domain, the model outputs present low values of the MBE (represented by Figs. 4 and 5c and d) for both NRF and RF simulations. During the dust episode the model underestimates MODIS AOD550 (MBE minimum values for NRF and RF simulations, respectively, −0.31 and −0.36) over the locations with significant dust loads (high AOD550) and overestimates (MBE maximum values 0.32 and 0.31) the low levels of AOD550. Although the bias is generally lower during the fire episode, a peak of positive bias (0.47 for both simulations) is evaluated over the Portugal fire area, thus the model overestimates AOD550 for biomass burning particles for both model configurations, including or not aerosol radiative feedbacks. However, we should bear in mind that this fact may be conditioned by the MODIS underestimation of AOD550 levels for high loads.
of this type of particle, which has been reported by Chu et al. (2002); Levy et al. (2005) and Remer et al. (2005), among others. On the other hand, a too high predicted AOD value by the model can generally be explained by the presence of either too much aerosol dry mass, too great a fraction of small particles for a given mass or an excess of water associated with the aerosols (Chapman et al., 2009).

With respect to the correlation coefficients (Fig. 4e and f for the dust episode and Fig. 5e and f for the fire episode), both simulations show high levels (around 0.9) of this statistical figure during the dust episode, except for those areas with high levels of AOD\textsubscript{550}, where the correlations are lower (even with negative correlations values close to \(-0.5\)). Conversely, for the fire episode, correlation values are close to 1 both for both cases (NRF and RF) over the entire domain, especially over the areas with high values of AOD\textsubscript{550}.

When considering the improvement (or not) of the AOD\textsubscript{550} when including aerosol radiative feedbacks in the simulations, the difference in the MAEs of the simulations between NRF and RF is estimated in Eq. (2). For the dust episode (Fig. 4b), a slight improvement (worsening) is produced over the areas with medium (high/low) levels of AOD\textsubscript{550}, taking these changes in values between \(-0.09\) and \(+0.12\). For the fire episode (Fig. 5b), a worsening of the MAE (difference NRF-RF of \(-0.02\)) is simulated close to the source of biomass burning aerosols. However, an improvement (up to \(+0.11\)) over areas further away from this source is estimated, which compensates for the importance of including aerosol feedbacks in the simulations when assessing the improvement or worsening of simulations.

In the case of the AE\textsubscript{550/860} from MODIS, the results are analogous for both episodes. Low values (<0.45, shown in Fig. 6a) of this variable over the south-east of the domain are found. This, together with the high levels of AOD\textsubscript{550} (Fig. 4a), is a clear indication that natural dust aerosols coming from the Sahara govern the AOD\textsubscript{550} levels here. On the
In this section, we evaluate the model output against AERONET data. First, a linear regression analysis is performed for AE at different wavelengths during the dust episode. The results indicate that the model shows higher skills in Barcelona and Sagres, with correlation coefficients of 0.96 and 0.84, respectively, compared to Caceres and Evora (correlation coefficients of 0.62 and 0.57, respectively) and for the fire episode, Caceres and Sagres (maximum correlation coefficient of 0.75) and, at Evora (0.66). At this point, it is important to note that this comparison is obtained between a point (AERONET) and a cell (model output) covering the corresponding station coordinates following a nearest approach. In spite of the use of this approach, small errors on the spatial distribution of the model variables can appear, producing lower correlation coefficients than those obtained in the comparison with AERONET data.}

### 3.3 Model output vs. AERONET data

This section shows the results of the comparison between model output and AERONET data. First, a linear regression is estimated (Figs. 6a, 6b, and 6c), and the results indicate that the model shows higher skills in Barcelona and Sagres (maximum correlation coefficient of 0.96 and 0.84, respectively), compared to Caceres and Evora (correlation coefficients of 0.62 and 0.57, respectively) and for the fire episode, Caceres and Sagres (maximum correlation coefficient of 0.75) and, at Evora (0.66). At this point, it is important to note that this comparison is obtained between a point (AERONET) and a cell (model output) covering the corresponding station coordinates following a nearest approach. In spite of the use of this approach, small errors on the spatial distribution of the model variables can appear, producing lower correlation coefficients than those obtained in the comparison with AERONET data.

### Table 2. Maximum AERONET AOD value at different wavelengths during the dust episode, the model output and AERONET data. First, a linear regression analysis is performed for the daily averages (Table 1). For the dust episode, the MBE (Fig. 6c) and MAE (Figs. 6d, 6e, and 6f) reach values of 0.68 and 0.66 for NRF and RF simulations, respectively, and the maximum MBE values around 0.65 and 0.6 for NRF and RF simulations, respectively. With respect to the correlation coefficient, the values of the statistic are lower than for AOD. The value of this statistic is lower for AOD than for other variables. AOD values are found to be low (<0.13). The correlation coefficient for the fire episode is higher (Figs. 6b, 6f, and 6g) for both simulations, the maximum MBE values, and the correlation coefficient are higher for NRF than for RF simulations (underestimation) and the maximum MBE values, and for the fire episode, the maximum MBE values, and the correlation coefficient are higher for NRF than for RF simulations (overestimation). Concerning the correlation coefficient, the value of this statistic is lower for AOD than for other variables. AOD values are found to be low (<0.13). The correlation coefficient for the fire episode is higher (Figs. 6b, 6f, and 6g) for both simulations, the maximum MBE values, and the correlation coefficient are higher for NRF than for RF simulations (underestimation) and the maximum MBE values, and for the fire episode, the maximum MBE values, and the correlation coefficient are higher for NRF than for RF simulations (overestimation).
values than the comparison with MODIS data, which is done cell (MODIS) versus cell (model output) with approximately the same resolution. Results do not indicate a clear improvement or worsening of both variables in both episodes when including the aerosol radiative feedbacks in our modelling configuration.

High levels of AERONET AOD are found between 2 and 10 of July 2010 due to the dust outbreak in Barcelona and Sagres (Fig. 11a and c). The time series of these stations have been selected as representative of all AERONET stations in the IP affected by the Saharan dust outbreak (see Supplement for information on the rest of AERONET stations over the IP). Maximum values of AERONET AOD occur between 7 and 10 July 2010. For AOD$_{1020}$, AOD$_{870}$ and AOD$_{675}$, the model underestimates the highest levels of AOD, represented by the minimum bias values (Table 2). On the other hand, between 2 and 6 of July 2010 (medium levels of AOD) the model overestimates the values of this parameter (Table 2). When an underestimation (overestimation) is produced, the bias is lower (higher) for lower wavelengths. The Sagres station lacks AOD$_{675}$ and AOD$_{440}$ data. Finally, the behaviour of AOD$_{440}$ in Barcelona is different from the other wavelengths due to the location of the station, close to a main street of the city where fine particles are emitted because of the road traffic.

For the fire episode, the stations shown are Caceres and Evora (see Supplement for the rest of the stations). In both stations, AOD presents the highest levels from 28 to 30 of July due to the wildfires that occurred in Portugal (Table 2). Except for the first 2 days, the model tends to underestimate the AOD values. For all wavelengths, the bias or error in both stations increases when the wavelength decreases.

Regarding the AE$_{440/870}$, for the dust episode the AERONET values show low values corresponding to large particles (generally between 0 and 1) in Sagres station, indicating the dust origin of the particles at this site. For the fire episode, values generally range between 1.5 and 2.5 at Evora station, revealing the small size of the biomass burning particles. Generally, for all stations in both episodes, the model overestimates (underestimates) AE$_{440/870}$ values when there are low (high) values of this variable. Hence, the model strongly underpredicts the variability of this variable for the two configurations.
Figure 8. Linear regression between AERONET (x) and simulation daily data (y; NRF in circles and RF in squares) for the dust episode (from 28 June to 12 July): AOD$_{1020}$ (top left), AOD$_{870}$ (top right), AOD$_{675}$ (bottom left) and AOD$_{440}$ (bottom right).

Figure 9. As Fig. 8 but for the fire episode (from 25 July to 7 August).
3.4 Model output vs. EARLINET data

Finally, the results of the comparison between the model output and EARLINET data are shown. In this section, only the dust episode is studied because the only station with available data for both study episodes in the IP during the year 2010 is Granada. At this site, dust has an important contribution to aerosol loads. Two specific days (6 and 12 July 2010) are shown for the sake of brevity, but this discussion is valid for other days of this episode. It is important to notice the differences between both discrete profile resolutions: the model profile, with 33 levels from the ground to approx. 20 km, and the profile measurement, which has a much higher vertical resolution (7.5 m). So the results below should be considered mainly from a qualitative perspective. However, in order to provide a more quantitative approach, the MAE of the model versus lidar observations is estimated.

As for the particle backscatter (BSCAT) at 532 nm for 6 July 2010 (Fig. 12a), the lidar detects a peak between $1.5 \times 10^{-6}$ m$^{-1}$ sr$^{-1}$ around 3250 m above sea level caused by a dust layer. Although the model outputs overestimate the BSCAT values, simulations capture the profile of BSCAT. Although NRF and RF model configurations perform similarly, there is a slight improvement of the MAE of the vertical profile (estimated after Eq. 3) when the aerosol radiative feedbacks are taken into account (Fig. 12a). Average MAEs are $6.37 \times 10^{-7}$ and $6.22 \times 10^{-7}$ m$^{-1}$ sr$^{-1}$ for NRF and RF simulations, respectively. Hence, the normalized MAE is improved by 2.4 % when aerosol radiative feedbacks are included in WRF-Chem simulations.

For the BSCAT for 12 July 2010 (Fig. 12b), the model overestimates the BSCAT values of the vertical profile, as mentioned above. However, the shape of the vertical profile is correctly reproduced. Mean MAEs are $3.14 \times 10^{-7}$ and $3.12 \times 10^{-7}$ m$^{-1}$ sr$^{-1}$ at 355 nm for NRF and RF simulations, respectively, and $4.1 \times 10^{-7}$ m$^{-1}$ sr$^{-1}$ at 532 nm for both cases. Here, the improvement when including aerosol radiative feedbacks is very limited and is estimated as 0.63 and 0.14 % at 355 and 532 nm.

4 Conclusions

The use of online coupled models is one of the most powerful ways of understanding the different processes influencing the climate system. In particular, for the study of atmospheric aerosol particles, realistic simulations of the combined ARIs and ACIs are needed, irrespective of the aerosols source, in which the interactions of aerosols, meteorology, radiation, and chemistry are coupled in a fully interactive manner. The use of modelling tools requires the observational study of physical, chemical and optical properties of aerosol particles to establish its behaviour and to assess how well these properties are represented in online coupled models.

In this study, two configurations with and without (RF/NRF simulations) the aerosol radiative feedbacks have been assessed against a number of remote-sensing observations for two episodes characterized by dust and biomass burning aerosols, respectively.

For the comparison between model output and MODIS data, the best-represented variable is AOD, with low values of mean bias and high values of correlation coefficient both for NRF and RF simulations. Discrepancies between simulations and observations can be ascribed to errors in the model estimation of the aerosol dry mass, the fraction of particles for a given mass or the water associated with aerosols. On the other hand, we should bear in mind the known errors from observations. The inclusion of the aerosol radiative feedbacks produces a slight improvement in the model representation for medium values of this variable and a worsening of the lowest and highest values. At the same time, the model output of AE representation leads to an underestimation of the variability of this variable. This occurred for both episodes and may be related to the fact that the size distribution of the aerosol function within WRF-Chem considers a medium size of particles, smaller for dust and larger for fire...
particles. The inclusion of aerosol feedbacks does not produce a clear benefit when taking into account the expensive computational cost required for including the ARIs and ACIs in the model. As well as for MODIS, for the comparison between model output and AERONET data, the results indicate that the best-represented variable is AOD. Generally, for both episodes, the model underestimates the levels of AOD, but the highest levels of this variable for dust episode are underestimated. It is important to note that the bias is usually higher for low wavelengths. In both episodes, the AE is overestimated for low levels and underestimated for high levels, since the modelled variability is strongly underestimated. For both variables, there is not a clear improvement in the model outputs for the aerosol radiative feedbacks simulation for any station in either episode.
For the comparison between model output and EARLINET data, the results show a general slight improvement in the representation of vertical aerosol profiles when the aerosol radiative feedbacks are taken into account for all studied wavelengths.

It is important to take into account these considerations to improve the time efficiency when running the simulations, because the inclusion of aerosol radiative feedbacks in the simulations causes a notable increase in computational time. The improvements observed, in particular those related to the vertical distribution of aerosols, justify the inclusion of aerosol radiative feedbacks in the WRF-Chem online coupled model and the much higher time devoted to running the simulations.

5 Data availability

The outputs from the simulations can be obtained by emailing the corresponding author (pedro.jimenezguerrero@um.es). AERONET data are publicly available from the AERONET website (http://aeronet.gsfc.nasa.gov/cgi-bin/type_piece_of_map_opera_v2_new). MODIS data are publicly available from the MODIS Atmosphere website (https://modis-atmos.gsfc.nasa.gov/MOD04_L2/acquiring.html).
