Abstract. We examine the past and future changes in the \(O_3\) outflow from East Asia using a global 3-D chemical transport model, GEOS-Chem. The simulations of Asian \(O_3\) outflow for 1986–2006 are driven by the assimilated GEOS-4 meteorological fields, and those for 2000–2050 are driven by the meteorological fields archived by the NASA Goddard Institute for Space Studies (GISS) general circulation model (GCM) 3 under the IPCC SRES A1B scenario. The evaluation of the model results against measurements shows that the GEOS-Chem model captures the seasonal cycles and interannual variations of tropospheric \(O_3\) concentrations fairly well with high correlation coefficients of 0.82–0.93 at four ground-based sites and 0.55–0.88 at two ozonesonde sites where observations are available. The increasing trends in surface-layer \(O_3\) concentrations in East Asia over the past 2 decades are captured by the model, although the modeled \(O_3\) trends have low biases. Sensitivity studies are conducted to examine the respective impacts of meteorological parameters and emissions on the variations in the outflow flux of \(O_3\). When both meteorological parameters and anthropogenic emissions varied from 1986–2006, the simulated Asian \(O_3\) outflow fluxes exhibited a statistically insignificant decadal trend; however, they showed large interannual variations (IAVs) with seasonal values of 4–9 \% for the absolute percent departure from the mean (APDM) and an annual APDM value of 3.3 \%. The sensitivity simulations indicated that the large IAVs in \(O_3\) outflow fluxes were mainly caused by variations in the meteorological conditions. The variations in meteorological parameters drove the IAVs in \(O_3\) outflow fluxes by altering the \(O_3\) concentrations over East Asia and by altering the zonal winds; the latter was identified to be the key factor, since the \(O_3\) outflow was highly correlated with zonal winds from 1986–2006. The simulations of the 2000–2050 changes show that the annual outflow flux of \(O_3\) will increase by 2.0, 7.9, and 12.2 \% owing to climate change alone, emissions change alone, and changes in both climate and emissions, respectively. Therefore, climate change will aggravate the effects of the increases in anthropogenic emissions on future changes in the Asian \(O_3\) outflow. Future climate change is predicted to greatly increase the Asian \(O_3\) outflow in the spring and summer seasons as a result of the projected increases in zonal winds. The findings from the present study help us to understand the variations in tropospheric \(O_3\) in the downwind regions of East Asia on different timescales and have important implications for long-term air quality planning in the regions downwind of China, such as Japan and the US.
1 Introduction

Tropospheric ozone (O\textsubscript{3}) is an important air pollutant that has a detrimental effect on human health (Fann et al., 2012; Jhun et al., 2014), crops (Wilkinson et al., 2011; Tai et al., 2014), and ecosystems (Fuentes et al., 2013; Yue and Unger, 2014). It is also an important greenhouse gas that directly contributes to global warming (IPCC, 2013). O\textsubscript{3} has a relatively long lifetime of weeks in the free troposphere (Young et al., 2013; Monks et al., 2015), which makes the intercontinental transport of O\textsubscript{3} an important issue for understanding O\textsubscript{3} concentrations and planning emission control measures.

A number of previous studies have shown that Asian continental outflow impacts the global O\textsubscript{3} budget (Liu et al., 2002) and influences O\textsubscript{3} air quality in the downwind regions from the western North Pacific to western North America (Jacob et al., 1999; Tanimoto et al., 2005; Kim et al., 2006; Li et al., 2008; Zhang et al., 2008; Chiang et al., 2009; Kurokawa et al., 2009; Huang et al., 2010; Nagashima et al., 2010; Walker et al., 2010; Ambrose et al., 2011; Lin et al., 2012; Ou-Yang et al., 2013; Han et al., 2015; Pochanart et al., 2015). Liu et al. (2002) reported that boundary-layer O\textsubscript{3} pollution was lifted into the upper troposphere by deep convection over the Asian maritime continent. From there, it was transported northward along the upper branch of the local Hadley circulation and into the mid-latitude westerlies, influencing the global O\textsubscript{3} budget. Using a global 3-D chemical transport model, GEOS-Chem, Zhang et al. (2008) estimated that Asian pollution enhanced surface-layer O\textsubscript{3} concentrations by 5–7 ppbv over western North America in spring 2006. Walker et al. (2010) used the same model (GEOS-Chem) to evaluate the sensitivities of tropospheric O\textsubscript{3} over Canada to Asian anthropogenic emissions and reported that the contribution from Asian emissions to O\textsubscript{3} profiles above Whistler, Canada was 6–8 ppbv in spring 2006. Through an integrated analysis of in situ and satellite measurements in May–June 2010 with a global chemistry–climate model, GFDL AM3, Lin et al. (2012) reported that Asian emissions could contribute 8–15 ppbv of O\textsubscript{3} over the western United States on days when the observed daily maximum 8 h average of O\textsubscript{3} (MDA8 O\textsubscript{3}) exceeded 60 ppbv. They also reported that 20 % of MDA8 O\textsubscript{3} exceedances of 60 ppbv would not have occurred in the southwestern United States in the absence of Asian anthropogenic emissions.

Asian O\textsubscript{3} outflow exhibits seasonal variations (Liu et al., 2002; Han et al., 2015). Using a global 3-D chemical transport model, GEOS-Chem, Liu et al. (2002) simulated the seasonal variations in the Asian outflow flux of O\textsubscript{3} over the Pacific, which was defined as the eastward flux integrated for the tropospheric column through a wall located at 150°E between 10 and 60°N. They found that the Asian O\textsubscript{3} outflow flux reached a maximum in early spring (March) and a minimum in summer (July). Han et al. (2015) examined O\textsubscript{3} measurements at the Ieodo Ocean Research Station located in the East China Sea, which is regarded as an ideal place to observe Asian outflow without local effects. They reported that the seasonal variation in O\textsubscript{3} was distinct, with a minimum in August and two peaks in April and October, and was greatly affected by the seasonal wind pattern over East Asia.

The continental outflow of O\textsubscript{3} is expected to vary on interannual to decadal timescales because tropospheric O\textsubscript{3} concentrations and meteorological parameters have variations on these timescales. Large interannual variations (IAVs) in tropospheric O\textsubscript{3} concentrations have been reported in previous observational studies (Kurokawa et al., 2009; Zhou et al., 2013). After analyzing 11 years of ozonesonde data over Hong Kong, Zhou et al. (2013) reported that observed tropospheric O\textsubscript{3} levels from 2000–2010 exhibited high IAVs with an annual averaged amplitude [defined as (maximum + 2nd maximum − minimum − 2nd minimum) × 0.5/the average from 2000–2010] of up to 30 % of the averaged concentrations at 3–8 km of altitude. Kurokawa et al. (2009) analyzed observed springtime O\textsubscript{3} over Japan from 1985–2005 and found that the observed O\textsubscript{3} showed greater year-to-year variations than the annual rate of the long-term trend. The decadal trends in tropospheric O\textsubscript{3} concentrations have been reported for different locations on the basis of observations (Ding et al., 2008a; Xu et al., 2008; Tang et al., 2009; Tanimoto, 2009; Wang et al., 2009b; Cooper et al., 2010; Wang et al., 2012; Lin et al., 2014, 2015; Zhang et al., 2014), such as −0.56 ppbv yr\textsuperscript{-1} over Lin’an in eastern China (Xu et al., 2008), +0.58 ppbv yr\textsuperscript{-1} over Hong Kong in southern China (Wang et al., 2009b), +1.0 ppbv yr\textsuperscript{-1} at Mount Hanno in Japan (for springtime O\textsubscript{3}; Tanimoto, 2009), and +0.35 ppbv yr\textsuperscript{-1} over Hawaii in the North Pacific (for autumn O\textsubscript{3}; Lin et al., 2014). Asian NO\textsubscript{x} emissions almost doubled over the past 20 years (Yang et al., 2015), which contributed to the increased O\textsubscript{3} observed over the regions downwind of Asia (Lin et al., 2017).

Future changes in tropospheric O\textsubscript{3} concentrations have also been predicted by modeling studies (Racherla and Adams, 2006, 2009; Lin et al., 2008; Wu et al., 2008a; Lam et al., 2011; Wild et al., 2012; Gao et al., 2013; Liu et al., 2013; Wang et al., 2013; Lee et al., 2015; Val Martin et al., 2015; Schnell et al., 2016; Zhu and Liao, 2016). Wang et al. (2013), using the NASA GISS GCM and GEOS-Chem model combination, reported that the summer surface-layer O\textsubscript{3} levels averaged over China would increase by 11.9 ppbv due to the combined changes in climate and emissions from 2000–2050 under the SRES A1B scenario.

Meteorological parameters, especially winds that are important for O\textsubscript{3} outflow, also exhibit variations on different timescales (Chang et al., 2000; Ding et al., 2008b; Sun et al., 2009; Zhang and Guo, 2010; Hirahara et al., 2012). Large IAVs in the East Asian monsoon (EASM) have been reported in previous studies (Zhu et al., 2012; Yang et al., 2014). The decadal-scale weakening of the EASM since the 1950s has also been reported by many previous studies, and anomalous northeasterlies during the weak monsoon years were found over the western North Pacific near 40°N, which...
did not favor the outflow of pollutants from northern China (Chang et al., 2000; Ding et al., 2008b; Zhu et al., 2012). On the basis of NCEP–NCAR reanalysis data, Sun et al. (2009) showed that the axis location of the East Asian subtropical westerly jet (EASWJ) had been displaced southward since the end of the 1970s, intensifying the westerly wind over 25–35° N and weakening it over 42–50° N, therefore influencing the outflow of pollutants. Lin et al. (2014) reported that the interannual variability in springtime Asian O₃ transport, as inferred by the East Asian COt (carbon monoxide-like tracer), was strongly influenced by ENSO-related shifts in the subtropical jet stream. They also reported that the decrease in ozone-rich Eurasian airflow reaching the eastern North Pacific in spring in the 2000s was attributed to more frequent La Niña events. Most of the models in the Coupled Model Intercomparison Project Phase 3 (CMIP3) predicted that the Asian jet would be intensified on its equatorward side by the end of the 21st century (Zhang and Guo, 2010; Hirahara et al., 2012). Few previous studies have examined the IAVs, decadal trends, and future changes in O₃ outflow. In this work, we examine the historical (1986–2006) and future (2000–2050) changes in the O₃ outflow from East Asia and systematically quantify the roles of meteorological parameters and/or anthropogenic emissions in the changes. The descriptions of the model, emissions, and numerical simulations are presented in Sect. 2. Section 3 evaluates the model performance for tropospheric O₃. Section 4 discusses the IAVs and the decadal trends in the O₃ outflow from East Asia from 1986–2006. Future changes in O₃ outflow from East Asia for 2000–2050 are presented in Sect. 5.

2 Methods

2.1 Model description

We apply the global 3-D chemical transport model GEOS-Chem to simulate O₃ outflow fluxes. The GEOS-Chem model includes a detailed simulation of O₃–NOₓ–hydrocarbon (~80 species, ~300 chemical reactions; Bey et al., 2001) and aerosol chemistry. Aerosol species include sulfate (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺; Park et al., 2004; Pye et al., 2009), black carbon (BC) and organic carbon (OC; Park et al., 2003), mineral dust (Fairlie et al., 2007), and sea salt (Alexander et al., 2005). The simulations account for the impacts of aerosols on the distributions and concentrations of O₃ through heterogeneous reactions and changes in the photolysis rates (Lou et al., 2014).

To simulate historical changes in the Asian outflow of O₃, the GEOS-Chem model is driven by the assimilated GEOS-4 meteorological fields from the Goddard Earth Observing System (GEOS) of the NASA Global Modeling and Assimilation Office (GMAO). We perform simulations for 1986–2006, which are the years with available GEOS-4 meteorological datasets. The version of the model used here has a horizontal resolution of 2° latitude by 2.5° longitude with 30 vertical layers.

To simulate future changes in O₃ outflow fluxes from 2000–2050, the GEOS-Chem simulation is driven by meteorological data from the National Aeronautics and Space Administration Goddard Institute for Space Studies (NASA GISS) general circulation model (GCM) 3 (Rind et al., 2007) for both the “present day” (represented by data from 1996–2005) and the future (2046–2055), following Wu et al. (2008b), Pye et al. (2009), Wang et al. (2013), and Jiang et al. (2013). Both the GISS and GEOS-Chem models used here have a horizontal resolution of 4° latitude by 5° longitude with 23 vertical layers.

2.2 Emissions

For simulations from 1986–2006, the global anthropogenic emissions of reactive nitrogen oxides (NOₓ), carbon monoxide (CO), and sulfur dioxide (SO₂) in the model are from the Emission Database for Global Atmospheric Research (EDGAR) (Olivier and Berdowski, 2001). The global emissions of non-methane volatile organic compounds (NMVOCs) are from the Global Emissions Inventory Activity (GEIA) (Picco et al., 1992). The global emissions of carbonaceous aerosols (BC and OC) follow Bond et al. (2007). Anthropogenic emissions of reactive NOₓ, CO, SO₂, NH₃, and NMVOCs over East Asia are overwritten by the emissions inventory of Streets et al. (2003) and Zhang et al. (2009). The IAVs in anthropogenic emissions are represented by globally gridded annual scaling factors as described by van Donkelaar et al. (2008) for NOₓ, CO, and NMVOCs. The biomass burning emissions are taken from the Global Fire Emissions Database (GFEDv3) (van der Werf et al., 2010) for 1997–2006. The biomass burning emission data before 1997 are unavailable due to the lack of datasets.

Figure 1 shows the evolution of anthropogenic and biomass burning emissions of O₃ precursors (NOₓ, CO, NMVOCs) summed globally and for Asia (60–150° E, 10° S–55° N) from 1986–2006. The global anthropogenic emissions of these precursors exhibited no significant trends, while the Asian anthropogenic emissions showed large increases over the past 2 decades. Relative to 1986, the Asian anthropogenic emissions of NOₓ, CO, and NMVOCs in 2006 had increased by 70.0, 42.1, and 50.9 %, respectively. Compared with anthropogenic emissions, biomass burning emissions had greater IAVs from 1997–2006. Figure 1 also shows the pathway for the global CH₄ abundance used in our simulations of O₃. The CH₄ mixing ratio in 1986 was 1672 ppb, which had increased by 6.3 % in 2006. Note that from 1996–2006 when NOₓ emissions and satellite NO₂ columns were simultaneously available, the trend in NOₓ emissions over East Central China (ECC; 110–123° E, 30–40° N) was +8.2 % yr⁻¹ on the basis of the emission inventory used in this study; this is close to the trend of +9.0 % yr⁻¹ in NO₂.
Table 1. The anthropogenic emissions\(^a\) of O\(_3\) precursors for the present day (the year 2000) and the future (the year 2050; under the SRES A1B scenario).

\end{array}
\]

\(^a\) Biomass burning emissions are included. \(^b\) Asia covers the domain of 60°–150° E, 10° S–55° N.

columns averaged for ECC on the basis of tropospheric NO\(_x\) vertical column density (VCD) data retrieved from GOME (1996–2002) and SCIAMACHY (2003–2006), which are available from www.temis.nl.

For future simulations from 2000–2050, the anthropogenic emissions of O\(_3\) precursors, including NO\(_x\), CO, and NMVOCs, are taken from Wu et al. (2008b). Those of NH\(_3\) and SO\(_2\) follow Pye et al. (2009). The future anthropogenic emissions of O\(_3\) precursors, aerosol precursors, and aerosols under the SRES A1B scenario are generated by the Integrated Model to Assess the Greenhouse Effect (IMAGE) socioeconomic model using growth factors for different species and countries (Streets et al., 2004). Table 1 shows the present-day (the year 2000) and the future (the year 2050) anthropogenic emissions of O\(_3\) precursors under the SRES A1B scenario. The global emissions of NO\(_x\), CO, and NMVOCs are projected to increase by 78.4, 26.4, and 89.4% from 2000–2050; Asian emissions are projected to increase by 159.6, 23.7, and 118.6%, respectively. Present-day methane mixing ratios are specified as 1750 ppbv on the basis of observations (Wu et al., 2008b). The future methane concentrations are set to 2400 ppbv, following the SRES A1B scenario (Pye et al., 2009).

The natural emissions of O\(_3\) precursors, including NO\(_x\) from lightning and soil and NMVOCs from vegetation, are calculated on the basis of the assimilated GEOS-4 meteorological fields and the GISS CGM 3 meteorological parameters. The lightning NO\(_x\) emissions follow Price and Rind (1992) with the NO\(_x\) vertical profile proposed by Pickering et al. (1998). The soil NO\(_x\) emission scheme in the GEOS-Chem model is based on the work of Yienger and Levy (1995) and Wang et al. (1998). The biogenic emissions of NMVOCs are calculated according to the Model of Emissions of Gases and Aerosols from Nature (MEGAN; Guenther et al., 2006). Figure 2 shows the evolution of natural emissions summed globally and for Asia from 1986–2006. Both global and Asian NO\(_x\) emissions from lightning exhibited large IAVs and significant increasing trends. It has been shown that a warming climate leads to increased lightning NO\(_x\) (IPCC, 2013). Compared with lightning NO\(_x\) emissions, NO\(_x\) emissions from soil showed smaller IAVs and no significant decadal trend. Both global and Asian biogenic emissions of NMVOCs have been shown to have large IAVs as a result of the changes in both vegetation and meteorological parameters (Fu and Liao, 2012). For future simulations from 2000–2050, the natural emissions of O\(_3\) precursors are listed in Table 2. The simulated emissions of lightning NO\(_x\), soil NO\(_x\), and biogenic VOCs are projected to increase by 18.8, 14.9, and 22.1% globally and by 16.7, 21.4, and 18.9% for Asia, respectively.

The effects of changes in the stratosphere–troposphere exchange (STE) of O\(_3\) are not included in this study for past or future simulations. The cross-tropopause O\(_3\) flux is represented by the synthetic O\(_3\) (Synoz) method (McLinden et al., 2000), which imposes a global annual mean cross-tropopause O\(_3\) flux of 500 Tg yr\(^{-1}\).

### Numerical experiments

To examine the respective and combined impacts of meteorological parameters, anthropogenic emissions, and biomass burning emissions on the IAVs and decadal trends in O\(_3\) outflow from East Asia from 1986–2006, we perform simulations for four cases (Table 3):

* The MetEmisB simulation is conducted for 1997–2006 owing to the unavailability of biomass burning emission data before 1997.

To identify the relative roles of future changes in meteorological parameters and emissions in 2000–2050 changes in the Asian O₃ outflow flux, another four simulations are carried out: (a) Met2000Emis2000, present-day climate and emissions; (b) Met2050Emis2000, future climate and present-day anthropogenic emissions; (c) Met2000Emis2050, present-day climate and future anthropogenic emissions; and (d) Met2050Emis2050, future climate and emissions. Both the future climate and anthropogenic emissions follow the IPCC SRES A1B scenario.

The mass flux of O₃ through the vertical plane along 135° E from 20 to 55° N from the surface to 100 hPa is used to quantify the Asian O₃ outflow. The metric of mass flux through a vertical plane was also used by Liu et al. (2002) to represent the Asian O₃ outflow and by Jiang et al. (2013) and Yang et al. (2015) to represent the Asian aerosol outflow. It should be noted that the O₃ outflow flux from East Asia includes the effects of emissions on different regions of the world owing to the relatively long lifetime (∼3 weeks) of O₃ (Fiore et al., 2002; Liao et al., 2006). However, Liu et al. (2002) found that anthropogenic sources in Asia made the largest contribution to the Asian outflow flux of O₃.

3 Model evaluation

The GEOS-Chem simulations of O₃ have been evaluated extensively for the US (Liu et al., 2006; Wu et al., 2008b; Zhang et al., 2008), Europe (Auvray and Bey, 2005; Liu et al., 2006; Kim et al., 2015), and China (Wang et al., 2013; Lou et al., 2014; Yang et al., 2014; Zhu and Liao, 2016). These studies showed that the GEOS-Chem model captured the magnitude and distribution of the surface-layer concentration and column burden of tropospheric O₃ fairly well. The vertical distributions of O₃ have also been evaluated by aircraft campaigns and ozonesonde measurements (Zhang et al., 2008; Walker et al., 2010; Wang et al., 2011), showing that the GEOS-Chem model closely reproduced the observed O₃ profiles.

Here, we conduct comparisons with measurements to evaluate whether the version of the GEOS-Chem model used...
in this study can capture the temporal variations in tropospheric O$_3$. We use the observations of tropospheric O$_3$ available in East Asia as summarized in Table 4. Observations at two sites (Minami-Tori-shima and Yonaguni-jima) are from the World Data Centre for Greenhouse Gases (WDCGG; http://ds.data.jma.go.jp/gmd/wdcgg/), and those at another two sites (Rishiri Island and Ogasawara) are from the Acid Deposition Monitoring Network in East Asia (EANET; www.eanet.asia/product/index.html). These are used to evaluate the simulated surface-layer O$_3$ concentrations. The four Japanese sites are “remote” sites in the downwind regions of China. Figure 3 compares the time series of monthly surface-layer O$_3$ mixing ratios simulated by MetEmisB with those measured by WDCGG and EANET. The simulated surface-layer O$_3$ levels agree well with observations at all four stations. The model captures the seasonal cycles and interannual variations of surface O$_3$ fairly well with high correlation coefficients of 0.82–0.93 (Table 4). Generally, the GEOS-Chem model can capture the high values in early spring or winter when the Asian O$_3$ outflow flux is the highest, but it overestimates the low values in summer when the Asian O$_3$ outflow is at a minimum.

To evaluate the simulated O$_3$ concentrations for the boundary layer and the middle and upper troposphere, we use the ozonesonde data at two Japanese sites from World Ozone and Ultraviolet Radiation Data Centre (WOUDC, http://www. woudc.org/). The information for the two sites (Naha and Tsukuba) is listed in Table 4. Figure 4 compares the time series of monthly O$_3$ mixing ratios simulated by MetEmisB with those measured by ozonesonde. Comparisons are shown for four altitudes in the troposphere. The GEOS-Chem model captures the seasonal cycles and interannual variations of tropospheric O$_3$ at all altitudes with correlation coefficients ranging from 0.68 to 0.88 for the Naha site and from 0.55 to 0.76 for the Tsukuba site. However, the agreement with ozonesonde in the lowermost layer (1000–850 hPa) seems to be poorer than that with WDCGG or EANET. It is noted that the ground-based measurements (WDCGG or EANET) and simulation results are calculated from continuous data, while the ozonesondes are regularly launched at a fixed local time with a typical frequency of 1–2 weeks (Tanimoto et al., 2015). The inconsistency in sampling time may be responsible for the poorer agreement with ozonesonde.

The increasing trend in surface-layer O$_3$ in East Asia over the past 2 decades was reported by previous studies (Ding et al., 2008a; Wang et al., 2009b; Xu et al., 2016). Figure 5 compares the simulated trends in seasonal or annual mean surface-layer O$_3$ concentrations from the MetEmis experiment with the observed trends collected from previous studies. The simulated O$_3$ concentrations exhibit statistically significant increasing trends at all sites except for Waliguan in winter, although the model underestimates the trends for some stations and seasons. The modeled O$_3$ trends were also reported to have low biases in previous studies (Tanimoto et al., 2009; Parrish et al., 2014; Strode et al., 2015). Parrish et al. (2014) compared O$_3$ trends simulated by three chemistry–climate models with observations at Asian sites and reported that one model captured less than one-third of the observed increasing trend, whereas the other two models suggested no significant increasing trends.

In general, the GEOS-Chem model can capture the seasonal cycles and interannual variations in tropospheric O$_3$ fairly well, although the model overestimates the low values in summer, indicating an overestimation of the Asian O$_3$ outflow in summer. The increasing trends in surface-layer O$_3$ in China over the past 2 decades can also be captured by the GEOS-Chem model, although the modeled O$_3$ trends have low biases.

$^a$ The correlation coefficient ($R$) between the observed and simulated monthly O$_3$ mixing ratios. $^b$ The normalized mean bias (NMB, %) between the observed and simulated monthly O$_3$ mixing ratios.
Figure 1. The evolution of annual anthropogenic and biomass burning emissions summed globally and for Asia (60–150° E, 10° S–55° N) for NOx (Tg N yr\(^{-1}\)), CO (Tg CO yr\(^{-1}\)), and NMVOCs (Tg C yr\(^{-1}\)) from 1986–2006. The blue squares represent anthropogenic emissions, and the red circles represent the sum of anthropogenic emissions and biomass burning emissions. The last panel shows the evolution of global CH\(_4\) abundance (ppbv) from 1986–2006.

4 Simulated Asian O\(_3\) outflow from 1986–2006

4.1 Seasonal patterns of Asian O\(_3\) outflow

Figure 6 shows the pressure–latitude cross sections along 135° E of the seasonal O\(_3\) outflow fluxes averaged from 1997–2006 in the MetEmisB simulation. The maximum O\(_3\) fluxes were found in the middle to upper troposphere, which is consistent with Liu et al. (2002) and Wang et al. (2009a). This could be attributed to the vertical distributions of both zonal winds and O\(_3\) concentrations. The westerlies strengthen with altitude with the strongest winds occurring around 200 hPa (known as the East Asian subtropical westerly jet; Ren et al., 2011). Concentrations of O\(_3\) are high in the upper troposphere over the mid-latitudes (Wang, 1999).

The seasonal mass fluxes through the meridional plane (along 135° E from 20 to 55° N and from the surface to 100 hPa) were calculated to be 509.6, 437.6, 126.6, and 268.7 Tg season\(^{-1}\) for December–January–February (DJF), March–April–May (MAM), June–July–August (JJA), and September–October–November (SON), respectively. Although the seasonal flux was the highest in DJF, the monthly O\(_3\) flux through the panel peaked in March and reached the nadir in July (not shown in Fig. 6). Such monthly variations in the Asian O\(_3\) outflow flux agreed with those in Liu et al. (2002). The maximum O\(_3\) outflow in March was caused by the combined effects of meteorological conditions, biomass burning emissions, and stratospheric O\(_3\) intrusion. The “warm conveyor belt” (WCB) airstreams, which export pollution from the Asian boundary layer to the free troposphere, and the mid-latitude prevailing westerly winds in the free troposphere that transport pollution from Asia to the northwestern Pacific were strongest during the early spring period (Eckhardt et al., 2004; Pochanart et al., 2004). The contribution from Asian biomass burning emissions to the O\(_3\) outflow was at a maximum in the spring and insignifi-
Figure 3. The time series of monthly surface-layer O$_3$ mixing ratios measured by WDCGG and EANET (the blue line) and simulated by MetEmisB (the red line). (a) Minami-Tori-shima and (b) Yonaguni-jima are WDCGG sites, and (c) Rishiri Island and (d) Ogasawara are EANET sites.

significant in other seasons (Liu et al., 2002). The stratospheric O$_3$ intrusion was also found to be the most effective in late winter and early spring (Danielsen and Mohnen, 1977; Mahlman and Moxim, 1978).

4.2 IAVs and decadal trends in Asian O$_3$ outflow

Figure 7a shows the simulated annual O$_3$ outflow fluxes through the meridional plane along 135$^\circ$ E from 20 to 55$^\circ$ N from the surface to 100 hPa from 1986–2006 in the Met, Emis, and MetEmis simulations. Figure 7b shows the associated deviation from the mean (DEV). The simulations of the O$_3$ outflow in Met, Emis, and MetEmis examined the effects of variations in the meteorological parameters alone, anthropogenic emissions alone, and both meteorological parameters and anthropogenic emissions, respectively. The outflow fluxes of O$_3$ with changes in anthropogenic emissions alone (the Emis simulation) exhibited a statistically significant ($P < 0.001$) increasing trend. However, the magnitude of the increasing trend was very small; the decadal trend in the Asian O$_3$ outflow flux in the Emis simulation was calculated to be +16.7 Tg decade$^{-1}$ (i.e., +1.2 % decade$^{-1}$) using a linear fit with the least-squares method. The DEV, defined as

$$\text{DEV} = 100\% \times \left( C_i - \frac{1}{n} \sum_{i=1}^{n} C_i \right) / \left( \frac{1}{n} \sum_{i=1}^{n} C_i \right),$$

where $n$ is the number of years examined ($n = 21$ for 1986–2006) and $C_i$ is the simulated O$_3$ outflow flux in year $i$, changed from $-1.3\%$ (in 1986) to $+1.4\%$ (in 2006), also indicating a small increasing trend in the O$_3$ outflow flux. With variations in the meteorological parameters alone (the Met simulation), the simulated O$_3$ outflow fluxes exhibited large IAVs but a statistically insignificant ($P > 0.05$) decadal trend of $-3.4\%$ decade$^{-1}$. The DEV values in the Met simulation ranged from $-8$ to $+16.5\%$. With variations in both anthropogenic emissions and meteorological parameters (the MetEmis simulation), the simulated O$_3$ outflow showed large IAVs but a statistically insignificant ($P > 0.05$) decadal trend of $-2.2\%$ decade$^{-1}$.

To analyze the IAVs in O$_3$ outflow fluxes, the decadal trend obtained from the linear fit was removed from the time series of simulated O$_3$ outflow fluxes, following the approach used in previous studies that examined the IAVs in aerosol outflow fluxes (Yang et al., 2015) and O$_3$ concentrations (Camp et al., 2003). The deviations from the mean of the detrended O$_3$ outflow fluxes from the Met, Emis, and MetEmis sim-
Figure 4. The time series of monthly O$_3$ mixing ratios measured by ozonesonde (the blue line) and simulated by MetEmisB (the red line). (a) Naha and (b) Tsukuba are ozonesonde sites from the WOUDC. The comparisons are shown for four altitude levels in the troposphere.

The IAVs in the O$_3$ outflow fluxes were further quantified with statistical variables of the mean absolute deviation (MAD) and the absolute percent departure from the mean (APDM), which have been used in previous IAV studies, such as Mu and Liao (2014), Lou et al. (2015), and Yang et al. (2015). The absolute IAVs in the O$_3$ outflow fluxes can
Figure 5. A comparison of the simulated trends in seasonal or annual mean surface-layer O$_3$ concentrations from the MetEmis experiment with observations for Hong Kong ($22.2^\circ$N, $114.3^\circ$E; 1994–2007; Wang et al., 2009b), Waliguan ($36.3^\circ$N, $100.9^\circ$E; 1994–2013; Xu et al., 2016), Beijing ($40.0^\circ$N, $116.5^\circ$E; 2001–2006; Tang et al., 2009), and Taiwan ($23.5^\circ$N, $121.0^\circ$E; 1994–2007; Lin et al., 2010). The simulated trend at the Waliguan site for the winter is statistically insignificant. The trends in the seasonal mean O$_3$ concentrations at the Taiwan station are unavailable.

Figure 6. The pressure–latitude cross sections along $135^\circ$E of the simulated seasonal O$_3$ outflow fluxes and zonal winds in four seasons averaged from 1997–2006 in the MetEmis simulation. The O$_3$ mass fluxes are shown by the colored shading (kg season$^{-1}$ m$^{-2}$), and the winds are represented by the contours (m s$^{-1}$). The positive values represent eastward fluxes, and the negative values represent westward fluxes.

Figure 7. The evolution of the following: (a) the annual O$_3$ outflow fluxes (Tg yr$^{-1}$) across the meridional plane along $135^\circ$E from 20 to 55$^\circ$N and from the surface to 100 hPa from 1986–2006 in the Met, Emis, and MetEmis simulations; (b) the associated deviations from the mean (%); and (c) the deviations from the mean (%) of the detrended O$_3$ outflow fluxes. The deviation from the mean (DEV) is defined in Sect. 4.2.

be quantified by the MAD, defined as

$$ \text{MAD} = \frac{1}{n} \sum_{i=1}^{n} |C_i - \frac{1}{n} \sum_{i=1}^{n} C_i|,$$

while the IAVs relative to the multiyear average outflow flux can be quantified by the APDM, defined as

$$ \text{APDM} = 100\% \times \text{MAD} \times \left( \frac{\sum_{i=1}^{n} C_i}{n} \right),$$

where $n$ is the number of years examined ($n = 21$ for years 1986–2006) and $C_i$ is the detrended O$_3$ outflow flux in year...
The MAD and APDM values of the detrended seasonal and annual O$_3$ outflow fluxes across the meridional plane along 135° E from 20 to 55° N from the surface to 100 hPa are shown in Fig. 8. The seasonal MAD and APDM values in the Emis simulation were close to zero, while those in the Met and MetEmis simulations were relatively large. The APDM values in the Met and MetEmis simulations were at a maximum in JJA and at a minimum in SON. The MAD and APDM values in the Met simulation were almost identical to those in the MetEmis simulation, which indicated again that the IAVs in the O$_3$ outflow fluxes were mainly dependent on the variations in meteorological conditions, rather than the variations in anthropogenic emissions. With variations in both the meteorological parameters and anthropogenic emissions, the seasonal APDM values were in the range of 4–9 % and the annual APDM value was 3.3 %.

Figure 9 shows the pressure–latitude cross sections of the MAD values along 135° E for detrended annual O$_3$ outflow fluxes from the Met, Emis, and MetEmis simulations. The O$_3$ outflow in the Met simulation exhibited large IAVs throughout the whole troposphere with MAD values greater than 0.2 kg yr$^{-1}$ m$^{-2}$. The MAD values increased with altitude, which could be attributed to the vertical distributions of the IAVs in the westerly winds (see the MAD values of the winds in Fig. 9a). The variations in anthropogenic emissions led to very small IAVs with MAD values less than 0.2 kg yr$^{-1}$ m$^{-2}$ (Fig. 9b) throughout the troposphere. With variations in both the meteorological parameters and anthropogenic emissions, the MAD values (Fig. 9c) showed almost identical magnitudes and spatial distributions to those in the Met simulation (Fig. 9a), indicating the dominant role of variations in meteorological conditions in the IAVs in the O$_3$ outflow.

Variations in meteorological conditions can influence the IAVs in the O$_3$ outflow fluxes by changing the O$_3$ concentrations over East Asia (Yang et al., 2014; Lou et al., 2015) and by altering the zonal winds (Kurokawa et al., 2009). The O$_3$ outflow flux is simulated to correlate positively with the zonal winds averaged over 20–55° N along 135° E with a high correlation coefficient of +0.71 for annual fluxes and zonal winds. The correlation coefficient between O$_3$ fluxes and zonal winds is calculated to be +0.96 in summer when the APDM values of O$_3$ outflow fluxes are at a maximum. The high correlation coefficients indicate that the variation in zonal winds is the key factor that leads to the large IAVs in O$_3$ outflow fluxes.
Table 5. Simulated present-day O$_3$ fluxes and projected changes from the present day (1996–2005) to the future (2046–2055) through the vertical plane along 135° E from 20 to 55° N and from the surface to 100 hPa due to future climate change alone, changes in anthropogenic emissions alone, and changes in both climate and emissions.

* The units are Tg season$^{-1}$ for seasonal fluxes and Tg yr$^{-1}$ for annual fluxes. The values in parentheses are percentage changes relative to the present-day fluxes.

4.3 Effect of variations in biomass burning emissions

The biomass burning emissions of the O$_3$ precursors exhibited large IAVs from 1997–2006 (Fig. 1). To analyze the impacts of biomass burning emissions on the IAVs in O$_3$ outflow fluxes, we compare the MAD and APDM values of detrended O$_3$ outflow fluxes from 1997–2006 in the MetEmis and MetEmisB simulations. The MAD (APDM) was calculated to be 31.17 Tg yr$^{-1}$ (2.35 %) in the MetEmis simulation and 31.82 Tg yr$^{-1}$ (2.36 %) in the MetEmisB simulation. The minor influence of biomass burning emissions on the IAVs in the O$_3$ outflow fluxes from East Asia was also supported by Voulgarakis et al. (2015). Furthermore, Lin et al. (2014) reported that meteorological variability, compared with the variability in biomass burning, was much more important for driving the IAVs in springtime O$_3$ at the Mauna Loa Observatory, a remote North Pacific site sensitive to Asian pollution outflow.

5 Future changes in Asian O$_3$ outflow for 2000–2050

In this part of the study, we quantify the future decadal changes in the Asian O$_3$ outflow from 2000–2050 under the SRES A1B scenario and examine the relative impacts of variations in climate and anthropogenic emissions on the changes. We conduct each simulation for 10 years driven by 1996–2005 meteorology to represent the present-day (the year 2000) climate and by 2046–2055 meteorological fields to represent the future (the year 2050) climate, following 1 year of model spin-up. All the results presented below are 10-year averages. The simulated present-day and future changes in seasonal and annual fluxes in O$_3$ across the vertical plane along 135° E from 20 to 55° N are summarized in Table 5.

5.1 Present-day O$_3$ outflow

The pressure–latitude cross sections along 135° E of the simulated present-day (Met2000Emis2000) seasonal O$_3$ outflow fluxes, driven by the meteorological inputs provided by GISS GCM 3, are shown in Fig. 10a. The magnitudes, spatial distributions, and seasonal variations agree closely with those driven by the assimilated GEOS-4 meteorological fields (Fig. 6). The O$_3$ outflow flux through the vertical plane is simulated to be 1877.1 Tg yr$^{-1}$ with GISS GCM 3 meteorology and 1342.5 Tg yr$^{-1}$ with the GEOS-4 assimilated meteorological fields, which indicates the reliability of the simulated present-day O$_3$ outflow fluxes.

5.2 Effect of future climate change

Relative to the present-day value, the 2050 annual outflow of O$_3$ is estimated to increase by 2.0 % (Table 5) as a result of climate change alone (Met2050Emis2000 minus Met2000Emis2000). The outflow of O$_3$ shows a slight decrease of 1.8 in DJF and of 3.8 % in SON, but a large increase of 14.5 in JJA and of 7.3 % in MAM. The spatial distributions of the projected changes in O$_3$ fluxes are consistent with those of the changes in zonal winds (Fig. 10b). The wind speed of the westerlies in DJF and SON decreases across the troposphere over 30–45° N, leading to reductions in the O$_3$ outflow fluxes. In contrast, increases in the zonal winds in JJA and MAM lead to increases in O$_3$ outflow fluxes throughout the troposphere over 30–45° N. Our projected future changes in the zonal winds are consistent with previous studies. By analyzing 18 CMIP5 models, Huang and Wang (2016) assessed the future changes in atmospheric circulation in spring over East Asia. They found that although different models projected different changes (even in sign) in the zonal winds, the ensemble mean of 5 better-skill models among the 18 CMIP5 models exhibited overall increases in the zonal winds throughout the whole troposphere in spring, which agrees with our simulation. Based on 31 (29)-model ensemble mean results, Jiang and Tian (2013) showed that
the westerlies along 135° E in winter (summer) were projected to weaken (strengthen). Such projected patterns of future changes in the westerlies in winter and summer are also captured by our model. The changes in O$_3$ concentrations also contribute to the changes in O$_3$ outflow; although the zonal winds are projected to increase north of 40° N in the upper troposphere in SON, the O$_3$ outflow fluxes are simulated to decrease because of the significant decreases in O$_3$ levels north of 40° N in the upper troposphere (Fig. S1 in the Supplement).

5.3 Effect of future changes in anthropogenic emissions

The annual outflow of O$_3$ through the vertical plane is simulated to increase by 7.9% relative to the present-day value (Table 5) as a result of the changes in anthropogenic emissions alone (Met2000Emis2050 minus Met2000Emis2000). Considering that the O$_3$ outflow with changes in anthropogenic emissions alone exhibits an increasing trend of 1.2% decade$^{-1}$ from 1986–2006 (Sect. 4.2), the increasing trend of 1.2% decade$^{-1}$ (i.e., 6.0% half-century$^{-1}$) is close to the value of 7.9% for the future half-century.

The projected future O$_3$ fluxes show increases in all seasons, which can be attributed to the increases in the O$_3$ concentrations at all altitudes over Asia and upwind regions (i.e., Europe and Central Asia; Fig. S1) as a result of the increases in the anthropogenic emissions of the O$_3$ precursors (NO$_x$ and NMVOCs) and CH$_4$ concentrations. NO$_x$ emissions in 2050 are projected to increase by 159.6% over Asia and by 78.4% globally, while NMVOCs emissions are projected to increase by 118.6% over Asia and by 89.4% globally under the SRES A1B scenario (Table 1). The CH$_4$ mixing ratios are projected to increase by 37.1% relative to the present-day value. The largest increases in O$_3$ outflow fluxes are located in the middle to upper troposphere (Fig. 10c) owing to the strong westerlies located here. It is noted that, in spite of the significant increases in emissions, the simulated surface-layer O$_3$ concentrations show slight decreases over the North China Plain in DJF, which subsequently leads to small decreases in the O$_3$ outflow fluxes at the surface layer over 30–40° N. In DJF, biogenic VOC emissions are especially low over the North China Plain, whereas anthropogenic NO$_x$ emissions are fairly high due to residential heating, leading to a low VOCs / NO$_x$ ratio in this region (Lou et al., 2010; Fu et al., 2012). Therefore, increases in NO$_x$ emissions lead to decreases in surface-layer O$_3$ concentrations over the North China Plain.

5.4 Effect of future changes in both climate and anthropogenic emissions

The annual outflow of O$_3$ through the vertical plane is projected to increase by 12.2% (Table 5) from 2000–2050 as a consequence of future changes in both climate and anthropogenic emissions (Met2050Emis2050 minus Met2000Emis2000). Climate change in DJF and SON slightly offsets the effects of changes in the anthropogenic emissions, while climate change in MAM and JJA enhances the effects of variations in anthropogenic emissions. When considering future changes in both emissions and climate, the projected O$_3$ outflow fluxes show increases throughout almost the entire troposphere along 135° E in all seasons (Fig. 10d).

6 Uncertainty discussion

There are some uncertainties in our simulations. First, the influence of the interannual variation in the stratosphere–troposphere exchange on tropospheric O$_3$ is not considered in this study. Terao et al. (2008) reported that the stratosphere–troposphere exchange had large impacts on the interannual variability in tropospheric O$_3$ over Canada and Europe, but the impact was much smaller over East Asia. The second is the uncertainty associated with the selection of the longitudinal transect. We calculate the O$_3$ flux through the vertical plane along 135° E because 135° E is the easternmost boundary of China (i.e., the Wusuli River in northeastern China). We also calculate the O$_3$ outflow flux along 120° E, which is closer to the ozone production region in central to eastern China, and find that the variations in O$_3$ fluxes calculated at 120° E are similar to those calculated at 135° E. With variations in both anthropogenic emissions and meteorological parameters (the MetEmis simulation), the simulated O$_3$ outflow shows large IAVs but a statistically insignificant ($P > 0.05$) trend. The conclusion is consistent with that drawn from the variations in O$_3$ outflow calculated at 135° E. Finally, projecting the future atmospheric circulation on regional scales has a large amount of uncertainty, which is undergoing continuous improvement.

7 Conclusions

We quantify the past and future changes in the O$_3$ outflow from East Asia using the global 3-D chemical transport model GEOS-Chem. The historical (1986–2006) simulations are driven by the assimilated GEOS-4 meteorological fields, and the future (2000–2050) simulations under the IPCC SRES A1B scenario are driven by the meteorological fields archived from GISS GCM 3. Sensitivity studies are conducted to examine the respective impacts of meteorological parameters and emissions on the variations in the outflow flux.

The measurements from WDCGG and EANET are used to evaluate the simulated surface-layer O$_3$ concentrations; the ozonesonde data from WOUDC are used to evaluate the simulated O$_3$ concentrations for the boundary layer and the middle and upper troposphere. Generally, the seasonal cycles and interannual variations in tropospheric O$_3$ concentrations are captured fairly well by the GEOS-Chem model with high
correlation coefficients of 0.82–0.93 at four ground-based sites and 0.55–0.88 at two ozonesonde sites. The increasing trends in surface-layer O3 concentrations in East Asia over the past 2 decades can also be captured by the GEOS-Chem model, although the modeled O3 trends have low biases. The simulated Asian O3 outflow flux peaks in early spring and reaches the nadir in summer. The maximum O3 fluxes are located in the middle to upper troposphere.

The IAVs and decadal trends in Asian O3 outflow are examined from 1986–2006. The simulated O3 outflow fluxes showed large IAVs but an insignificant decadal trend; with variations in both meteorological parameters and anthropogenic emissions, the seasonal APDM values were in the range of 4–9 %. The sensitivity simulations showed that the large IAVs of the O3 outflow fluxes were mainly caused by the variations in meteorological conditions, rather than the variations in anthropogenic and biomass burning emissions. Although variations in the meteorological parameters could influence the IAVs in the O3 outflow fluxes by changing the O3 concentrations over East Asia and by altering the zonal winds, the latter was identified to be the key factor because of the high correlation coefficient of +0.71 between the annual fluxes and the zonal winds.

The decadal changes in the Asian O3 outflow are also examined from 2000–2050. The present-day annual O3 flux through the vertical plane is calculated as 1877.1 Tg, which is projected to change from 2000–2050 by +2.0, +7.9, and +12.2 % due to climate change alone, emissions change alone, and changes in both climate and emissions, respectively. In MAM and JJA, climate change plays a larger role in the future changes in O3 outflow compared with emissions changes, owing to the significant increases in the zonal winds in these two seasons. It is noted that climate change will aggravate the impacts of increases in anthropogenic emissions on the O3 outflow from East Asia from 2000–2050 under the SRES A1B scenario.

These findings are helpful for understanding the temporal evolution in the tropospheric O3 on different timescales in the

Figure 10. (a) The pressure–latitude cross sections along 135° E of the simulated present-day O3 mass fluxes and zonal winds (Met2000Emis2000). The projected changes in O3 mass fluxes and zonal winds from the present day (1996–2005) to the future (2046–2055) caused by (b) climate change alone (Met2050Emis2000 minus Met2000Emis2000), (c) changes in anthropogenic emissions alone (Met2000Emis2050 minus Met2000Emis2000), and (d) changes in both climate and anthropogenic emissions (Met2050Emis2050 minus Met2000Emis2000). The O3 mass fluxes are shown by the colored shading (kg season$^{-1}$ m$^{-2}$), and the winds are represented by the contours (m s$^{-1}$). The dotted areas are statistically significant at the 95 % level, as determined by a two-sample Student’s t test.
downwind regions of East Asia. The observed IAVs in tropospheric \( \text{O}_3 \) on a relatively short timescale can be attributed to variations in the meteorological parameters. Furthermore, the conclusions from this study will have important implications for long-term air quality planning for the regions downwind of China, such as Japan and the US. Since future climate change will increase the \( \text{O}_3 \) outflow from East Asia, extra efforts are needed to reduce the anthropogenic emissions of \( \text{O}_3 \) precursors to offset the adverse effects caused by climate change.

Data availability. GEOS-Chem is an open-access model developed collaboratively at Harvard University and other institutes in North America, Europe, and Asia. The source codes can be downloaded from http://acmg.seas.harvard.edu/geos/. The tropospheric \( \text{NO}_2 \) vertical column density (VCD) data are retrieved from GOME (1996–2002) and SCIAMACHY (2003–2006), which are available from www.temis.nl. The \( \text{O}_3 \) measurements at Minami-Tori-shima and Yonaguni-jima are available from the World Data Centre for Greenhouse Gases (WDCGG; http://ds.data.jma.go.jp/gmd/wdgg/). Those at Rishiri Island and Ogasawara are available from the Acid Deposition Monitoring Network in East Asia (EANET; www.eanet.asia/product/index.html). The ozone sondes data at Naha and Tsukuba are available from the World Ozone and Ultraviolet Radiation Data Centre (WOUDC; www.woudc.org). All data presented in this study are available upon request from the corresponding author.

The Supplement related to this article is available online at doi:10.5194/acp-17-3729-2017-supplement.

Author contributions. Hong Liao and Jia Zhu conceived the study and designed the experiments. Jia Zhu performed the simulations, carried out the data analysis, and prepared the paper. Yuhao Mao provided useful comments on the paper. Yang Yang and Hui Jiang helped with performing the experiments.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This work was supported by the National Basic Research Program of China (973 Program, grant no. 2014CB441202) and the National Natural Science Foundation of China under grants 91544219 and 41475137. We acknowledge the free use of GOME and SCIAMACHY tropospheric \( \text{NO}_2 \) vertical column density (VCD) data available from www.temis.nl. The following data centers are also acknowledged: the World Data Centre for Greenhouse Gases (WDCGG; http://ds.data.jma.go.jp/gmd/wdgg/) operated by the Japan Meteorological Agency (JMA) in cooperation with the World Meteorological Organization (WMO); the World Ozone and Ultraviolet Radiation Data Centre (WOUDC; www.woudc.org) operated by Environment Canada for the Global Atmosphere Watch (GAW) program of the WMO. The Rishiri Island and Ogasawara sites are operated by the Ministry of the Environment of Japan as part of the Acid Deposition Monitoring Network in East Asia (EANET; www.eanet.asia/product/index.html). We are also very grateful to the reviewers for their helpful comments and thoughtful suggestions.
