Abstract. This review paper explores recent efforts to estimate state- and national-scale carbon dioxide (CO₂) and methane (CH₄) emissions from individual anthropogenic source sectors in the US. Nearly all state and national climate change regulations in the US target specific source sectors, and detailed monitoring of individual sectors presents a greater challenge than monitoring total emissions. We particularly focus on opportunities to synthesize disparate types of information on emissions, including emission inventory data and atmospheric greenhouse gas data.

We find that inventory estimates of sector-specific CO₂ emissions are sufficiently accurate for policy evaluation at the national scale but that uncertainties increase at state and local levels. CH₄ emission inventories are highly uncertain for all source sectors at all spatial scales, in part because of the complex, spatially variable relationships between economic activity and CH₄ emissions. In contrast to inventory estimates, top-down estimates use measurements of atmospheric mixing ratios to infer emissions at the surface; thus far, these efforts have had some success identifying urban CO₂ emissions and have successfully identified sector-specific CH₄ emissions in several opportunistic cases. We also describe a number of forward-looking opportunities that would aid efforts to estimate sector-specific emissions: fully combine existing top-down datasets, expand intensive aircraft measurement campaigns and measurements of secondary tracers, and improve the economic and demographic data (e.g., activity data) that drive emission inventories. These steps would better synthesize inventory and top-down data to support sector-specific emission reduction policies.

1 Introduction

Government regulations of greenhouse gas (GHG) emissions have evolved rapidly in the past 5 years, particularly in the US. The US pledged to decrease its GHG emissions by 26–28% relative to 2005 levels by 2025 as part of the Paris Agreement negotiated at COP21 (UNFCCC, 2016). In parallel with this agreement, the US Environmental Protection Agency (EPA) has finalized CO₂ and CH₄ emission regulations for numerous source sectors under the White House Climate Action Plan (Executive Office of the President, 2013). Several US states have also taken aggressive action on emissions, including Massachusetts (Massachusetts Executive Office of Energy and Environmental Affairs, 2015) and California (Air Resources Board, 2014), among others.

These policy actions require scientists and government agencies to quantify regional- and national-scale GHG emissions from specific source sectors. In this paper, we define a source sector as the total emissions from an industry, such as CO₂ from power plants, CH₄ from the oil and natural gas industries, or CH₄ from landfills. This review paper focuses on existing and evolving capabilities for the US. The US has far greater resources to estimate emissions relative to many developing countries. Furthermore, GHG emission regulations in the US are nascent relative to regulations in Europe (e.g., Prahl and Hofman, 2014), and the monitoring strategies discussed in this review could be developed in parallel with new regulations.

Many national emission regulations in the US target this sector level (Note: the new presidential administration that assumed office in January 2017 has announced its intention to discard several of these regulations.). For example, the US Clean Power Plan mandates a 32% decrease in power sector CO₂ emissions by 2030 relative to 2005 levels (US EPA,
in the past decade (US Energy Information Administration, 2015a). The EPA and National Highway Traffic Safety Administration have also extended and strengthened CO₂ emission standards for cars and light trucks through 2025 (US EPA Office of Transportation and Air Quality, 2012). In addition to these measures, the EPA has set several sector-specific CH₄ emission targets. In May of 2016, the EPA issued a rule that will decrease CH₄ emissions from oil and gas operations by 40–45% relative to 2012 levels by 2025 (US EPA, 2016a). In August of 2014, the US EPA, US Department of Agriculture (USDA), and US Department of Energy (DOE) released the Biogas Opportunities Roadmap targeting voluntary reduction strategies for agriculture (USDA et al., 2014). Lastly, the EPA announced regulations for CH₄ emissions from landfills in July 2016 (EPA, 2016b). It is important to note that a number of these national policies are implemented at the state level. For example, each state has a different emission reduction target under the Clean Power Plan, and each state can decide how to meet and monitor progress toward that target (US EPA, 2015a).

We examine sector-specific GHG estimates with an eye toward combining or assimilating multiple data streams. This review article is part of a special issue of the European Geophysical Union (EGU) journals that focus on data assimilation and the use of multiple data streams to understand the carbon cycle. In this context, we explore opportunities to creatively synthesize both bottom-up emission inventories and top-down atmospheric inverse modeling. Most government agencies estimate emissions using bottom-up inventories, which quantify total emissions by estimating the total amount of some activity and the average emissions per unit of activity. Other efforts utilize top-down atmospheric inverse modeling, which measures atmospheric GHG mixing ratios and use those measurements to infer the level and distribution of emissions at the Earth’s surface. In the future, scientists and government agencies will likely need to combine these approaches into frameworks that can synergistically leverage the information content of bottom-up datasets and top-down strategies using atmospheric GHG data to robustly estimate sector-specific emissions. This review paper focuses on these opportunities.

These frameworks will need to address two key tasks: estimating the total quantity of GHG emissions from each source type and detect changes or trends in emissions from that source type. From the standpoint of inverse modeling, the former problem is more challenging than estimating total emissions and requires separating the space–time patterns of one emission source from the patterns of other sources. In the latter case, we not only need to estimate a trend in total emissions but also to attribute this trend to trends in specific source sectors. This challenge is complicated by changes in technology and changes in the spatial or temporal distribution of individual source sectors. For example, hydraulic fracturing and horizontal drilling became widely used in the past decade (US Energy Information Administration, 2015). These operations utilize new equipment and opera-

These challenges are further complicated by GHG fluxes from the biosphere, particularly in the case of CO₂. Biospheric and fossil fuel sources will be important to disaggregate from one another for sound policy evaluation. These sources are often colocated and trends in one could be mistaken for trends in the other. In addition, future changes in biospheric CO₂ and CH₄ sources may be natural or human-caused (e.g., land use change, emissions induced by climate change, biological and/or geological carbon sequestration). Disentangling these natural and human causes will be challenging. Note that GHG fluxes from the biosphere and biological–geological carbon sequestration are beyond the scope of this review.

In this article, we explore the challenge of estimating sector-specific emissions from several perspectives. First, we discuss bottom-up inventory efforts. We then explore top-down strategies to estimate sector-specific emission and the atmospheric datasets available to make both bottom-up and top-down estimates. Next, we highlight several new or novel approaches for estimating sector-specific emissions, and lastly, we close the review with a synthesis discussion of forward-looking opportunities for combining bottom-up and top-down strategies.

### 2 Bottom-up data

Bottom-up efforts typically use an accounting-type approach to estimate sector-specific emissions. The first step usually involves collecting activity data: a map or database of economic activity or behavior that leads to emissions. Examples include the amount of coal burned by power plants, the number of passenger cars and miles traveled, and the number of cows by location. A second step entails estimating a set of emission factors (EFs) for each activity. EFs could include the CO₂ emissions per kilogram of coal burned or the average CO₂ emissions per mile traveled by passenger cars. The product of these two numbers provides a bottom-up estimate of emissions for a given source sector. State and national governments in the US use this strategy to construct official emission estimates (e.g., California Air Resources Board, 2015; US EPA, 2016c). A number of academic and government efforts have produced bottom-up CO₂ and CH₄ emission estimates at local–regional (e.g., Gately et al., 2013; Jeong et al., 2014; Lyon et al., 2015; California Air Resources Board, 2015), national (e.g., Pétron et al., 2008; Gurney et al., 2009; Gately et al., 2015; US EPA, 2013; Environment and Climate Change Canada, 2016; Maasakkers et al., 2016), and global scales (e.g., Rayner et al., 2010; Andres et al., 2011; Oda and Maksyutov, 2011; Olivier et al., 2014; EC JRC/PBL, 2016). In this section, we primarily discuss...
bottom-up data with an eye toward how this information can be combined with top-down strategies.

2.1 A prototypical example

We describe the EPA’s estimate of CO$_2$ emissions from coal-fired power plants as a prototypical example of how government agencies construct bottom-up inventory estimates. The EPA describes the procedure that it uses to estimate CO$_2$ emissions in compliance with 2006 IPCC guidelines (US EPA, 2016c): first, the agency estimates activity data – coal use by source sector. The EPA uses retail statistics from the electricity sector to estimate total consumption by each type of end user (e.g., residential, commercial). Second, the EPA adjusts these activity data to account for non-combustion uses, double-counted emissions, and fuel exports and/or imports. For example, a coal gasification plant in North Dakota produces synthetic natural gas; this fuel is added to natural gas activity data and subtracted from the coal activity data. According to the EPA, “Because this energy of the synthetic natural gas is already accounted for as natural gas combustion, this amount of energy is deducted from the industrial coal consumption statistics to avoid double counting” (US EPA, 2016a). Third, the EPA estimates the carbon content of the coal. The EPA uses Energy Information Administration (EIA) estimates of carbon content by coal rank and state of origin (Hong and Slatick, 1994). The EPA then computes the weighted average carbon content of coal by state of origin and estimates the end use of coal produced in each state (e.g., electricity, industry). The agency uses this procedure to estimate the average carbon content (and EF) for each end use sector in the US (US EPA, 2016c).

IPCC guidelines also require a reference approach: an additional verification or consistency check against fuel production, imports, and exports (US EPA, 2016c). The new draft inventory then goes through expert review undertaken by a panel of technical experts. The EPA revises its inventory estimate based upon this review and distributes the subsequent draft for public comment. At the conclusion of that process, the EPA issues its finalized inventory estimate.

The approach outlined above is similar to many government inventories. More recently, a number of academic efforts have developed very different approaches that leverage novel data streams (e.g., satellite images of lights at night) or that use gridded activity data, and these efforts are described in detail in the next section.

2.2 Recent bottom-up efforts

In the past 10 years, inventory efforts have moved from coarse estimates that rely heavily on proxy activity data to spatially resolved estimates that use specific activity data and EFs that are tailored to the heterogeneities in each emission source.

A number of recent CO$_2$ inventories incorporate more comprehensive activity data or detailed EFs than previously available. At the regional scale, Gurney et al. (2012) and Gately et al. (2013) develop on-road CO$_2$ emission estimates for Indianapolis and Massachusetts, respectively. Emissions in the latter study are within 8.5% of Federal Highway Administration fuel consumption statistics but differ from the commonly used, global-scale EDGAR inventory by 22.8% (Olivier et al., 2014; EC JRC/PBL, 2016). The authors explain that many global-scale efforts use road density as a proxy for vehicle emissions but argue that the relationship between road density and emissions is not constant. Two subsequent studies (McDonald et al., 2014; Gately et al., 2015) estimate on-road CO$_2$ emissions for the entire US at spatial resolutions down to 1 km$^2$. McDonald et al.’s 2014 emission estimates differ from EDGAR by 20–80% at the municipal level, though the two inventories produce nearly identical national totals.

At the national scale, the VULCAN inventory (Gurney et al., 2009) is the most comprehensive academic effort to date. This inventory includes CO$_2$ emissions by sector at high spatial and temporal resolutions – 10 km × 10 km – sub-daily for the year 2002. Furthermore, VULCAN uses more detailed activity data than the EPA’s national inventory. At the global scale, the EDGAR anthropogenic emission inventory (available for 1970–2010) has moved from a 1° × 1° lat–long resolution to 0.1° × 0.1° (Olivier et al., 2014; EC JRC/PBL, 2016). In a separate effort, Andres et al. (2011) estimate CO$_2$ emissions for 80 countries for the years 1950–2006, with a particular focus on estimating the seasonal cycle of CO$_2$ emissions.

A number of studies incorporate more detailed activity data and EFs to estimate anthropogenic CH$_4$ emissions at both regional and national scales. At the regional scale, Jeong et al. (2014) and Lyon et al. (2015) estimate oil and gas CH$_4$ emissions from California for 2010 and the Barnett Shale region for 2013, respectively. Both studies find emissions that greatly exceed the EPA’s estimates. A relatively small fraction of emitters account for the majority of oil and gas emissions, and Lyon et al. (2015) argue that rigorous EFs capture this skewed distribution more effectively than those used by the EPA. In addition to these oil and gas inventories, Owen and Silver (2015) compile field studies of CH$_4$ emissions from agriculture (e.g., cattle, sheep, and manure management). The authors explain that current emission inventories use EFs from lab-based experiments, not field observations. These field observations imply much higher EFs that result in larger emissions, which are more in line with existing top-down estimates. At the national scale, Maasakkers et al. (2016) create a gridded version of the EPA’s CH$_4$ inventory (0.1 × 0.1 lat–long, monthly resolution for 2012). Maasakkers et al. (2016) point out that the spatial distribution of their estimate is different from EDGAR, particularly for the oil and gas industries. Oil and gas emissions in EDGAR correlate with population density, while emis-
A number of additional studies also employ novel inventory methodology or novel proxy datasets. For example, Oda and Maksyutov (2011) develop ODIAC (Open-source Data Inventory of Anthropogenic CO$_2$), a global gridded CO$_2$ inventory constructed using a database of CO$_2$ point sources and satellite images of lights at night. Rayner et al. (2010) and Asehi-Najafabady et al. (2014) develop a data assimilation framework known as FFDAS (Fossil Fuel Data Assimilation System). The authors use datasets like population density, carbon intensity of energy, and satellite images of lights at night, and they report national emission totals. Davis and Caldeira (2010) use a very different approach from any of the studies above. The authors build a CO$_2$ estimate based upon economic imports and exports and explore the idea of carbon “leakage”, the carbon emitted by one country to manufacture products that are then imported by another country. These studies do not provide emission estimates for each individual source sector, but ODIAC and FFDAS do incorporate novel datasets to separate point sources (e.g., power plants) from non-point emissions.

The EPA’s GHG Reporting Program (GHGRP) represents an important advancement in government inventory efforts. The EPA announced the GHGRP in 2009 and emission reporting began in 2010 (US EPA, 2013). The GHGRP requires all entities that emit over 25 000 metric tons of CO$_2$ equivalents to report their emissions to a national registry (US EPA, 2013). This reporting threshold is equivalent to the GHG emissions of 3439 homes or 5263 cars (US EPA, 2015c). The agricultural sector is excluded from this threshold and is not required to report its emissions. Despite these omissions, the EPA estimates that 85–90% of US GHG emissions are covered under the GHGRP. Other recent studies, however, argue that the GHGRP is less complete than estimated by the EPA for two reasons (e.g., Kort et al., 2014; Karion et al., 2015; Lan et al., 2015; Lavoie et al., 2015; Mitchell et al., 2015; Subramanian et al., 2015; Zimmerle et al., 2015). First, the emissions that are excluded from the GHGRP are sometimes larger than estimated by the EPA, and second, the EFs used in the GHGRP are smaller than actual emissions from some source sectors like oil and natural gas.

2.3 Recent, direct measurements that support bottom-up efforts

Inventory development requires two different types of data: activity data and data that can be used to develop EFs. Activity data can come from economic, census, and remote sensing datasets, among other possible data sources. These datasets differ from those used to develop EFs. The IPCC provides a database of EF estimates but encourages countries to take measurements of emitters or emitting processes to develop tailored, country-specific EFs (Goodwin et al., 2006). A number of observation strategies can directly support the development and evaluation of country-specific EFs. We discuss a number of recent efforts here as well as the advantages and challenges of using these datasets.

One observation strategy is to measure GHG mixing ratios near an emitter or a group of emitters. These observations, by factor of their targeted spatial scale, can be directly used to evaluate a single source type and develop corresponding EFs. For example, a number of studies report on direct GHG measurements from individual facilities. These include direct stack measurements of power plant CO$_2$ emissions (e.g., Teichert et al., 2003) and numerous recent studies of CH$_4$ emissions from oil and gas operations: measurements of emissions from pneumatic controllers (Allen et al., 2015), compressor stations (Subramanian et al., 2015), transmission and storage systems (Zimmerle et al., 2015), and abandoned wells (Kang et al., 2014). In addition, several site-level studies target agricultural emissions. Kebreab et al. (2008) and Sejian et al. (2010) review several measurement strategies, and Owen and Silver (2015) specifically review field studies of CH$_4$ emissions from manure.

On-road measurements provide a picture of emissions that is one spatial scale larger than direct facility observations. This strategy usually entails measuring trace gas mixing ratios from a ground-based vehicle either on public roads (e.g., Maness et al., 2015) or private roads in partnership with the facility owner (e.g., Roscioli et al., 2015). Existing studies often target oil and gas facilities (e.g., Roscioli et al., 2015; Brantley et al., 2014; Jackson et al., 2014; Lan et al., 2015; Mitchell et al., 2015; Subramanian et al., 2015) and mobile CO$_2$ emissions (e.g., Brondfield et al., 2012; Maness et al., 2015). In the case of oil and gas emissions, Brantley et al. (2014) explain that mobile measurements capture an integrated plume that includes all leaks from a given facility but rarely indicate which components caused those leaks.

The use of facility-level and on-road observations entails a number of challenges. For example, facility-level observations provide the most insight into detailed emission processes from specific source sectors but can miss emission events or processes. Observations of oil and gas facilities provide a prime example; scientists may not know about some leaks and therefore may not measure them, other leaks may be in inaccessible locations (e.g., Subramanian et al., 2015), and the largest leaks often come from ephemeral equipment failures at a small number of facilities that are difficult to identify (e.g., Brantley et al., 2014; Allen, 2014; Allen et al., 2015). Cost also limits facility-level, continuous emission monitoring; it is typically only used for large point sources like power plants (National Research Council, 2010).

These observation strategies also require extrapolation to produce state- or national-scale EF estimates. The relationship between activity data and emissions can be complex and spatially variable, making it difficult to extrapolate facility or on-road measurements. For example, CH$_4$ emissions from oil and gas are likely dominated by a small number of malfunctioning facilities. As a result, it is difficult to develop robust,
national-scale EFs from a modestly sized sample of facilities (Allen, 2014). Furthermore, Brantley et al. (2014) explain that these leaks do not correlate with production and can vary greatly in time. Different oil and gas drilling basins also have different overall leakage rates – from 0.3 % in Pennsylvania’s Marcellus Shale region to 8.9 % in Utah’s Uintah Basin (e.g., Karion et al., 2013, 2015; Pétron et al., 2014; Peischl et al., 2015). These factors make it challenging to create consistent, generalizable EFs that can translate activity data into emissions.

These considerations also apply to other source sectors beyond the oil and gas industries. For example, grazing and manure management practices differ by region, and manure and landfill CH$_4$ emissions also vary by climate (US EPA, 2016c), all of which make extrapolation more challenging.

### 2.4 Impact of recent advances

Inventory estimates of sector-specific CO$_2$ emissions from the US are likely relatively accurate at the national scale but have substantial uncertainties at the local and state levels. Ackerman and Sundquist (2008), for example, compare smokestack versus fuel-based CO$_2$ estimates for US power plants and find a mean absolute difference of 16.6 % but only a 1.4 % total difference at the national scale. Furthermore, Gatley et al. (2015) find biases of 100 % or more at the urban scale in CO$_2$ emission estimates for mobile sources. However, they estimate a US national total that is broadly consistent with other inventories like VULCAN.

By contrast, sector-specific CH$_4$ emissions are more challenging to estimate and existing inventories for the US are highly uncertain at state and national scales. For example, several top-down studies indicate that the California state inventory is likely too low by a factor of 1.2 to 1.9 (Jeong et al., 2013, 2016; Wecht et al., 2014b), and several top-down studies estimate emissions for oil and gas drilling regions of Utah and Colorado that are up to 3 times bottom-up estimates (e.g., Karion et al., 2013; Pétron et al., 2014). Overall, total US CH$_4$ emissions are likely ~50 % larger than estimated by EDGAR or the US EPA (Miller et al., 2013; Wecht et al., 2014a; Turner et al., 2015). Figure 1 compares several inventory estimates of sector-specific CO$_2$ and CH$_4$ emissions. Existing CO$_2$ inventory estimates are broadly consistent, while CH$_4$ estimates vary between inventories and among inventory versions.

CH$_4$ inventories are so uncertain, in part, because of the complexity of many anthropogenic CH$_4$ source sectors. For example, emission factors for oil and gas operations are difficult to estimate because a small number of emitters often account for a large fraction of emissions (e.g., Allen, 2014; Allen et al., 2015; Brantley et al., 2014; Lan et al., 2015; Mitchell et al., 2015) and because there are so many points along the natural gas production, processing, transmission, and distribution cycle that leak methane (e.g., Kang et al., 2014; Allen et al., 2015; McKain et al., 2015; Subramanian et al., 2015; Zimmerle et al., 2015).

Much of the uncertainty in CH$_4$ inventories stems from difficulties developing accurate EFs. Brandt et al. (2014) explains, “... measurements for generating emission factors are expensive, which limits sample sizes and representativeness. Many EPA EFs have wide uncertainty bounds. And there are reasons to suspect sampling bias in EFs, as sampling has occurred at self-selected cooperating facilities.” For example, the EPA’s EFs for natural gas pipelines are based on a limited number of samples from a 1996 EPA and Gas Research Institute study; these EFs have uncertainties of ±65 % (Beusse et al., 2014). Beyond the oil and gas industry, Owen and Silver (2015) also argue that many EFs for agriculture are too low. These estimates are based upon a small number of pilot or lab experiments that were not explicitly designed for GHG inventory development.
3 Top-down, inverse modeling strategies

In this section, we discuss inverse modeling strategies – strategies that leverage observations of atmospheric GHG mixing ratios to infer emissions at the Earth’s surface. We specifically focus on strategies that attempt to parse the contribution of specific source sectors. The first part of this discussion (Sect. 3.1–3.2) focuses on efforts at local, urban, and regional scales. These studies do not provide direct state- or national-level estimates but could be combined or extrapolated to quantify emissions at larger spatial scales. Many studies in this category target source sectors that do not overlap spatially, at least at the spatial scale of interest. The second part of this discussion (Sect. 3.3–3.4) explores inverse modeling efforts that directly quantify sector-specific emissions at the state and national levels. These efforts use observation networks that are sensitive to emissions across broad geographic regions. These efforts must also devise strategies to disentangle emissions from multiple, spatially overlapping source sectors.

3.1 Local-scale inverse modeling

Local-scale inverse modeling can best attribute emissions when the study region has a single, dominant source type. An estimate of total emissions for the region thus provides insight into the source sector of interest.

Studies that fall within this category often employ one of a few different strategies to estimate emissions. For example, many efforts use a simple box-modeling approach to estimate emissions (e.g., Turnbull et al., 2011; Karion et al., 2013, 2015; Caulton et al., 2014; Schneising et al., 2014; Cambaliza et al., 2015; Peischl et al., 2015), while others use an atmospheric transport model to relate GHG observations to emissions (e.g., McKain et al., 2012, 2015). Studies that use the former strategy typically estimate emissions in a few steps: first, they make GHG measurements upwind and downwind of the region of interest. Second, they use the difference between these measurements, the rate of flow through the “box” (i.e., wind speed adjusted by pressure), and the volume of the box (i.e., the area of the box and the mixing height of the atmosphere) to calculate total emissions in the box. Most studies that use box modeling estimate a total flux for the region of interest, a number that is not spatially resolved.

Other studies in this category use a more involved approach: they model atmospheric GHG mixing ratios using an emission inventory and an atmospheric transport model. Subsequently, these studies scale the inventory using a single scaling factor (β) to better match modeled mixing ratios against measured mixing ratios:

\[
y_k = \sum_{j=1}^{m_s} h_{k,j}(x_j^a) + \epsilon_k \tag{1}
\]

\[
x_j^a = \beta x_j^b. \tag{2}
\]

In these equations, \(y_k\) is an atmospheric GHG observation at a given time and location \(k\). It is one of \(n\) total observations \((k = 1 \ldots n)\). The variable \(x_j\) denotes the emissions from a model grid box \(j\) at a specific location and time, and the function \(h_{k,j}(\cdot)\) is an atmospheric transport model that relates the surface emissions from grid box \(j\) to observation \(y_k\). The variable \(m_s\) denotes the total number of model grid boxes in space, and \(m_t\) denotes the number of time periods. In one study, this emission estimate varies both spatially and temporally (McKain et al., 2012), and in another study, the emission estimate varies spatially but was constant in time \((m_t = 1; \text{McKain et al., 2015})\). The superscripts \(a\) and \(b\) denote an emission inventory and final emission estimate, respectively. In addition, the variable \(\epsilon_k\) denotes the cumulative error in the model and measurement (e.g., error in the estimated transport, in the measurement, and in the estimated emissions, among other errors). The objective of this approach is to scale an inventory estimate using a single scaling factor (β) so that modeled atmospheric mixing ratios on the right-hand side of Eq. (1) reproduce the \(n\)-observed atmospheric mixing ratios \((y_k \text{ where } k = 1 \ldots n)\).

These local-scale efforts can target sources with very large emissions or very uncertain emissions. For example, many existing studies target emissions from cities. Cities account for 70% of global fossil fuel CO₂ emissions; thus, insight into urban emissions provides insight into a large fraction of total anthropogenic GHG emissions (US Energy Information Administration, EIA). Note that studies in this category generally do not discriminate among different urban source sectors but can provide insight into the contribution of urban CO₂ sources versus power plant CO₂ sources (which often occur well outside city limits). Existing efforts estimate CO₂ emissions for Indianapolis, Indiana (Mays et al., 2009); Sacramento, California (Turnbull et al., 2011); and Salt Lake City, Utah (McKain et al., 2012), as well as CH₄ emissions from Boston, Massachusetts (McKain et al., 2015), and Indianapolis (Cambaliza et al., 2015). McKain et al. (2012) and McKain et al. (2015) use the approach in Eq. (1), while the other studies implement box models.

Other studies in this category target oil and natural gas industry emissions. Existing studies use aircraft observations to estimate CH₄ emissions from Utah’s Uintah drilling basin (Karion et al., 2013); southwest Pennsylvania (Caulton et al., 2014); Colorado’s Denver–Julesburg Basin (Pétron et al., 2014); the Barnett Shale in Texas (Karion et al., 2015; Lavoie et al., 2015); and the Haynesville, Fayetteville, and Marcellus Shale regions (in Texas, Arkansas, and Pennsylvania, respectively) (Peischl et al., 2015). In addition to these aircraft-based studies, one study uses the SCIAMACHY instrument
on the Envisat satellite to estimate CH$_4$ emissions from the
Eagle Ford and Bakken Shale regions in Texas and North
Dakota, respectively (Schneising et al., 2014). Several of
these studies find leakage rates that greatly exceed the EPA’s
estimated emission factors (e.g., Karion et al., 2013; Pétron
et al., 2014; Schneising et al., 2014), while other studies esti-
mate leakage rates that are comparable to the EPA’s numbers
(e.g., Caulton et al., 2014; Peischl et al., 2015). Differences
in drilling technology and practices from one basin to another
may account for these contrasting results (e.g., Peischl et al.,
2015).

These local-scale inverse modeling studies confer a num-
ber of advantages relative to other top-down strategies. These
strategies capture emissions from all facilities in a given re-

gion, including those with anomalously high emissions. In
the past, the EPA has had difficulty designing facility-level
measurements that adequately sample these anomalous emi-
ters (Sect. 2.4). An additional advantage of these strategies is
their ease of implementation relative to those discussed in
subsequent sections (Sect. 3.3–3.4). Box modeling requires
an estimate of air flow into and out of the box, but this ap-

does not require a full atmospheric transport model.

Furthermore, the strategies discussed in this section are not as
computationally intensive as many of the state- and national-
scale strategies discussed later in Sect. 3.3.

These strategies also bring a number of challenges. Nearly
all of the oil and gas studies listed above use data from a sin-
gle measurement campaign and provide a temporal snapshot
of emissions. GHG emission reduction policies make it nec-
essary to monitor trends, a goal that requires sustained mon-
itoring. In addition, a locality or region must have one domi-
nant source sector or have spatially (or temporally) nonover-
lapping source sectors in order to attribute emissions using
this strategy (e.g., Hutyra et al., 2014; Peischl et al., 2015).
For example, Peischl et al. (2015) estimate oil and gas emis-
sions from drilling regions that also contain livestock, land-
fills, and wastewater treatment facilities, all of which produce
CH$_4$ emissions. The authors subtract an inventory estimate
of these non-hydrocarbon CH$_4$ sources from their estimated
emission total, and they attribute the remaining emissions to
oil and gas activities. The authors point out that these non-oil
and gas source sectors are small contributors relative to oil
and gas operations (8.5–19 % of the CH$_4$ emission total in
each region), and uncertainties in these other source sectors
would likely have a small impact on their oil and gas emis-
sion estimate.

Complex environmental conditions and the associated at-
mospheric transport errors can also pose a challenge for
local-scale inverse modeling strategies, particularly for box
models. A simple box modeling setup can be difficult to ap-
ply when atmospheric advection, vertical mixing, or upwind
“clean air” measurements are highly heterogeneous across
the box. For example, Turnbull et al. (2011) report that their
CO$_2$ budget for Sacramento, estimated using a box model,
is uncertain by a factor of 2 due to uncertainties in estimated
wind speed and upwind clean air mixing ratios. Furthermore,
Karion et al. (2015) estimate CH$_4$ emissions for the Bar-
nett Shale that vary from $4.4 \times 10^4$ to $10.9 \times 10^4$ kg h$^{-1}$,
depending on the flight. However, the authors explain that
two of the eight flights occurred during nonideal meteorolo-
gical conditions, and the range of estimates narrows to
$6.1 \times 10^4$ to $8.8 \times 10^4$ kg h$^{-1}$ when those flights are excluded
from the analysis. Atmospheric transport models can simu-
late more complex atmospheric transport patterns relative to
box models but still have difficulty modeling local- or urban-
scale phenomena, including small-scale turbulent eddies, air
flow through street canyons, and vertical mixing in a human-
built landscape (e.g., Nehrkorn et al., 2013). These modeling
challenges also apply to the state- and national-scalestrategies
discussed in Sect. 3.3–3.4. New innovations in atmo-
spheric monitoring and instrumentation may reduce some of
these uncertainties. Calcambiza et al. (2014), for example,
explain that lidar instruments can measure atmospheric mixing
height, and lidar deployment could therefore improve certain aspects of atmospheric modeling, particularly at lo-
cal and regional scales. In addition, several studies develop
high-resolution meteorological simulations, in part to better
resolve atmospheric GHG transport in urban environments
(e.g., McKain et al., 2012, 2015; Nehrkorn et al., 2013).

3.2 Observations that support local-scale inverse
modeling

Many recent, local-scale observation efforts focus on urban
monitoring and on oil and gas basins. Existing urban, at-
mospheric measurement networks include Salt Lake City,
Utah (McKain et al., 2012); Los Angeles, California (Duren,
2016); Oakland, California (Cohen, 2016), the Bay Area Air
Quality Management District (Fairley and Fischer, 2015); and
Indianapolis, Indiana (Mays et al., 2009; Calcambiza et al.,
2015; Lauvaux et al., 2016). Recent local-scale aircraft
campaigns include the INFLUX campaign focused on the
Indianapolis metro region (Calcambiza et al., 2015), the
SENEX and SONGNEX campaigns focused on multiple oil
and gas drilling basins (Peischl et al., 2015; NOAA Chem-
ical Sciences Division, 2016), and the Barnett Coordinated
Campaign (Smith et al., 2015; Karion et al., 2015; Fig. 2).
In addition to these urban and oil and gas studies, Lindenmaier
et al. (2014) and Frankenberg et al. (2016) use spectroscopic
CO$_2$ and CH$_4$ observations, respectively, to identify emis-
sions from resource extraction in the Four Corners region of
the western US.

The observational strategies described above are relatively
diverse. These efforts include a combination of aircraft and
stationary sites (e.g., telecommunication towers or building
rooftops). Some of these campaigns provide a 1- or 2-day
snapshot in time (e.g., most oil and gas studies), while other
campaigns involve sustained measurements over 1 year or
more (e.g., urban observation networks like LA Megacities
and the Indianapolis INFLUX project).
sector-specific emissions. Each approach, however, uses a different mix; the first approach relies most heavily on existing inventories, while the last relies most on GHG observations.

Overall, these strategies have been relatively successful at attributing CH4 emissions, but promising strategies for CO2 are nascent. Biospheric CO2 fluxes are large relative to anthropogenic CO2 emissions at diel to monthly timescales, particularly during the growing season, and the spatiotemporal distribution of these fluxes is highly uncertain (e.g., Huntzinger et al., 2012). These factors have limited the success of CO2-focused efforts.

The first strategy discussed here scales the individual source sectors in a bottom-up inventory. This setup is often similar to a multiple linear regression:

$$x_j^a = \sum_{i=1}^{p} \beta_i x_j^{b},$$

where $i$ denotes an individual source sector from a bottom-up inventory, and $p$ indicates the total number of source sectors in the inverse model. The observational constraint ($y_k$) in this approach is the same as in Eq. (1). This setup also assumes that the initial emission estimate ($x_{j,i}^b$, where $j=1...m_s \cdot m_t$ and $i=1...p$) is defined at each $m_s$ spatial location, at each $m_t$ time period, and for each $p$ source sector. In one study, this initial emission estimate is spatially but not temporally resolved (e.g., Zhao et al., 2009), while in another study, it is resolved in both space and time (Jeong et al., 2013). The $p$ unknown scaling factors ($\beta_i$, where $i=1...p$) adjust the magnitude of different source sectors in the bottom-up inventory; these factors are estimated by the inverse model. As a result of this setup, the estimated emissions ($x_{j,i}^a$) will always be a linear combination of source-specific emission patterns in an existing bottom-up inventory. Studies that use this approach often estimate the scaling factors ($\beta_i$) using Bayesian statistics; these frameworks can weigh uncertainty in the measurements ($y_k$) and in the atmospheric model ($h_{k,j}$) against uncertainty in the initial or prior guess for the scaling factors (typically one; e.g., Rayner et al., 2016).

A handful of studies leverage this approach to attribute emissions of CH4. For example, Zhao et al. (2009) and Jeong et al. (2013) use atmospheric measurements from tall towers to estimate emissions from individual source sectors in California. Both studies find higher CH4 emissions from agriculture relative to the EDGAR emission inventory.

This scaling factor approach brings several strengths and weaknesses. An advantage of this approach is that it not only provides an estimate of total emissions but also the contributions of individual source sectors. The approach can be relatively easy to implement from a statistical perspective. With that said, one still needs to run an atmospheric transport model and must have an estimate of background or upwind, clean air mixing ratios.

3.3 State- and national-scale inverse modeling

The top-down strategies discussed in this section provide sector-specific GHG emission estimates across larger regions, regions that typically have several overlapping source sectors. Furthermore, these strategies make spatially variable adjustments to existing inventories, unlike the strategies outlined in Sect. 3.1. The three strategies discussed in this section use both GHG observations and inventories to attribute...
A notable challenge of this strategy is that it requires accurate knowledge of the spatial distribution of each source sector. The estimated emissions will always be a linear combination of source-specific emission patterns from an existing inventory, and errors in the spatial distribution of these inventories will propagate into errors in sector-specific attribution. Furthermore, the atmospheric GHG observations \( \gamma_k \) must be sensitive to differences in the space–time patterns among different source sectors. Worded differently, each of the \( p \) source sectors must have differing spatiotemporal patterns, and each sector must explain substantial variability of the observations \( \gamma_k \). If the former condition does not hold, then some of the \( p \) source sectors will be collinear; collinearity can lead to unphysical scaling factors \( \beta_i \) and unrealistically large uncertainty estimates (e.g., Zucchinì, 2000). If the latter condition does not hold, then the scaling factors may be poorly constrained by the data, resulting in uncertain or unrealistic sector-specific estimates. To account for these challenges, Jeong et al. (2013) only report source-specific estimates when they obtain scaling factors that are statistically significantly different from zero.

A second common inverse modeling strategy scales an emission inventory at the model grid level to better reproduce the atmospheric observations \( \gamma_k \). All of the strategies discussed previously scale the spatial patterns in an existing inventory. By contrast, this strategy scales the emission level at each location in the model domain, and the resulting estimate can have spatial patterns that are different from any inventory. These estimates have the following general form:

\[
x^j = \beta_j x^j.
\]

(4)

Note that \( x^j \) and \( x^j \) are the total emissions from model grid box \( j \), not the emissions by sector. Hence, the scaling factors \( \beta_j \), where \( j = 1 \ldots m \cdot m_i \) adjust total emissions, and all of the \( m \cdot m_i \) factors are typically estimated simultaneously. Several studies estimate scaling factors that vary spatially but are the same at each time step (e.g., Wecht et al., 2014a, b; Turner et al., 2015). One study allows the scaling factors to vary in both space and time (Jeong et al., 2016). This approach is also Bayesian in nature: the modeler sets an initial guess for the scaling factors (typically unity) and an uncertainty in that initial guess; this information guides the initial guess for the scaling factors (typically unity) and an uncertainty can lead to unphysical scaling factors \( \beta_i \) and unrealistically large uncertainty estimates (e.g., Zucchinì, 2000). If the latter condition does not hold, then the scaling factors may be poorly constrained by the data, resulting in uncertain or unrealistic sector-specific estimates. To account for these challenges, Jeong et al. (2013) only report source-specific estimates when they obtain scaling factors that are statistically significantly different from zero.

This strategy has a number of advantages and weaknesses relative to other approaches. The strategy can be used to estimate emissions at grid scale, and the resulting emission estimate will not be a linear combination of existing inventory estimates. However, it assumes that the inventory has correctly estimated the relative magnitude of each emission source in each model grid box. Errors in this relative magnitude will produce errors in the sector-specific attribution.

Third, a number of studies leverage a strategy known as geostatistical inverse modeling (GIM) to estimate GHG fluxes generally (e.g., Michalak et al., 2004; Goudjì et al., 2008, 2012) and anthropogenic emissions specifically (Miller et al., 2013, 2016; Shiga et al., 2014; ASCENDS Ad Hoc Science Definition Team, 2015; Yadav et al., 2016). This approach attributes patterns in the emissions to individual anthropogenic source sectors when possible. However, it will leave emissions as unattributable when those emissions do not match the space–time patterns in any bottom-up inventory or when the information content of the atmospheric observations is insufficient for attribution:

\[
x^j = \sum_{i=1}^{p} \beta_i x^j_{i,i} + \xi_j.
\]

(6)

The elements \( x^j_{i,j} \) can be individual source sectors from a bottom-up inventory (similar to Eq. 3). The inverse model will then map the emissions onto those patterns to the extent possible. The inverse model will further add (or subtract) emissions at the model grid scale to better reproduce the atmospheric observations \( \gamma_k \). These emissions are denoted by \( \xi_j \) (where \( j = 1 \ldots m \cdot m_i \)), and a GIM typically labels the emissions in \( \xi_j \) as unattributable. Furthermore, existing studies allow \( x^j_{i,j} \) and \( \xi_j \) to vary both spatially and temporally with \( j \), in contrast to the studies described earlier in this section. Note that existing GIM studies fix the coefficients \( \beta_i \)
in both space and time. In reality, the relationship between $x_{j,i}^b$ and GHG emissions may vary spatially and temporally by grid box $j$. Two recent GIM studies experiment with allowing the coefficients to vary by region or biome in the context of anthropogenic (Shiga et al., 2014) and biospheric (Fang and Michalak, 2015) fluxes.

Several studies leverage this strategy in the context of both anthropogenic CH$_4$ and CO$_2$ emissions. Miller et al. (2013) use a GIM and in situ atmospheric measurements to estimate sector-specific CH$_4$ emissions in the US; like Turner et al. (2015), they find higher emissions from the agriculture and oil and gas sectors relative to inventory estimates. Miller et al. (2016) also use this strategy to separate CH$_4$ emission patterns due to wetlands from anthropogenic emissions and to evaluate bottom-up estimates of the former emission category. Two studies (Shiga et al., 2014; ASCENDS Ad Hoc Science Definition Team, 2015) implement a GIM-based framework to identify anthropogenic CO$_2$ emission patterns using in situ and satellite CO$_2$ observations. They investigate whether the atmospheric signal resulting from anthropogenic CO$_2$ emissions can be reliably identified given the confounding signal from biospheric CO$_2$ fluxes. They find that in situ and remote sensing CO$_2$ networks can only identify anthropogenic emissions in a few regions during a few months of the year.

The GIM approach makes more conservative assumptions relative to other source attribution strategies discussed in this section. A GIM will only attribute emissions to patterns in a bottom-up inventory when that inventory matches patterns in the atmospheric GHG observations. In Miller et al. (2013), for example, the GIM maps 60% of total US CH$_4$ emissions onto patterns in the EDGAR inventory but indicates that 40% of the total emissions are unattributable to the patterns in any bottom-up dataset. By contrast, the other approaches discussed above will attribute 100% of the emissions. In GIM studies like Miller et al. (2013), the unattributable emissions indicate shortfalls in either the GHG observation network or available bottom-up data. In the former case, existing atmospheric observations do not provide enough information to reliably estimate sector-specific emission patterns. For example, the information content of the atmospheric observations in Miller et al. (2013) is insufficient to uniquely constrain emissions from coal mining, and those emissions are included in $\xi_j$ instead of $\sum_{j=1}^b \beta_i x_{i,j}^b$. In the latter case, the unattributable emissions in $\xi_j$ indicate inaccuracies in the spatial distribution of available inventory estimates. Many existing inventories do not have well-developed activity data for the oil and gas industry, and the unattributable emissions in Miller et al. (2013) provide information about shortfalls in these activity datasets.

Yadav et al. (2016) modify the existing GIM framework to better isolate anthropogenic CO$_2$ emissions. The authors exploit differences in the spatiotemporal properties of biospheric versus fossil fuel fluxes to do this attribution. Specifically, the authors argue that biospheric fluxes have smooth spatiotemporal patterns, and fossil fuel emissions do not have smooth patterns. The authors then partition $\xi_j$ into two components (smooth and non-smooth) and attribute these emissions to the biosphere and fossil fuels, respectively. The study examines emissions in January when biospheric fluxes are smaller than in other months.

In summary, this section discusses statistical innovations that help isolate individual emission sources. In addition to these innovations, accurate models of atmospheric transport also play a crucial role. A number of studies indicate the deleterious influence of transport errors. For example, Shiga et al. (2014) argue that atmospheric transport errors hinder the detection of fossil fuel emission patterns across the US. The authors also argue that biospheric fluxes mask fossil fuel patterns to a similar degree. Numerous additional studies examine the effects of transport errors on CO$_2$ modeling, though not in the context of fossil fuel emissions (e.g., Stephens et al., 2007; Liu et al., 2012; Miller et al., 2015).

Several efforts could reduce these transport modeling errors. Like urban-scale studies (Sect. 3.1), national inverse modeling studies have also begun moving toward high-resolution meteorology simulations. These studies simulate atmospheric GHG transport at high resolution over the US and Canada and utilize coarser resolutions elsewhere to save on computational costs. For example, national-scale studies using the Weather Research and Forecasting (WRF) model model GHG transport at resolutions of up to 8–10 km (Nehrkon et al., 2010; Gourdji et al., 2012; Miller et al., 2013), and studies using the GEOS-Chem model simulate CH$_4$ transport at resolutions of up to ~50 km (e.g., Wecht et al., 2014a; Turner et al., 2015). In addition to these efforts, NASA’s Atmospheric Carbon and Transport – America campaign (ACT–America, Fig. 2a) aims to diagnose and reduce atmospheric transport errors (NASA, 2016). The campaign includes new tower sites and 5 years of aircraft flights across the eastern US. Many flights will travel through frontal systems and extratropical cyclones to better characterize and evaluate atmospheric transport errors.

3.4 Observations that have been used to attribute emissions at state and national scales

The observations discussed in this section do not provide a direct constraint on an individual source sector but have been used by existing regional- and national-scale inverse modeling studies (Sect. 3.3) to support sector-specific attribution. These observations are typically distributed across a broad geographic region. They are therefore sensitive to emissions over a large area and can constrain larger regions, albeit with less detail than the local approaches discussed in Sect. 3.2.

Observations in this category include air samples collected atop telecommunication towers and from aircraft: the NOAA tall-tower observation network (Andrews et al., 2014), regular NOAA aircraft monitoring (Sweeney et al., 2015), the Environment and Climate Change Canada tower monitoring
network (Environment and Climate Change Canada, 2011), the California Greenhouse Gas Research Monitoring Network (e.g., Zhao et al., 2009; Jeong et al., 2012, 2013, 2016), and a privately funded tower network operated by Earth Networks (Fig. 2). Most of the inverse modeling studies discussed in the previous section (Sect. 3.3) use these in situ observation networks to estimate sector-specific emissions (Zhao et al., 2009; Jeong et al., 2013; Miller et al., 2013; Shiga et al., 2014; ASCENDS Ad Hoc Science Definition Team, 2015; Jeong et al., 2016).

The current tower network is sensitive to emissions from some source sectors but not to others. Many of the NOAA tall towers and regular aircraft sites are in or near the Great Plains. As a result, the network has sensitivity to agricultural emissions and to several oil and gas basins but has little sensitivity to emissions from east coast population centers. Earth Networks, by contrast, has focused its efforts on the east coast proximal to large population centers. The state of California has a dense network of publicly operated towers. In contrast to these regions, the network is sparse across the western US outside of California and northern Colorado. On the one hand, the population in these regions is sparse and some emission sectors are likely to be small (e.g., vehicle emissions). On the other hand, large resource extraction regions are beyond reach of the long-term monitoring network, regions like the Powder River basin coal mining region of Wyoming or the Bakken oil and gas basin in Montana and North Dakota.

NOAA’s regular aircraft monitoring network complements these tower-based sites. The flights measure GHG mixing ratios across a vertical atmospheric profile. These datasets can help evaluate vertical mixing and transport in atmospheric transport models, and observations from the middle and upper troposphere can be used to quantify background clean air mixing ratios, a necessity for the inverse modeling studies described in Sect. 3.3. A downside is that NOAA’s aircraft profiles are usually limited in frequency to one or two times per month, unlike towers, which often have continuous observations. Scientists at NOAA have also invented a technology known as AirCore that can observe vertical atmospheric GHG profiles from a weather balloon (Karion et al., 2010). This technology could become a key component of the long term monitoring network in the future.

A number of intensive aircraft campaigns provide observations across entire state or multi-state regions (Fig. 2). These include the 2010 CalNex campaign (Ryerson et al., 2013), the 2013 SEAC4RS campaign (Toon et al., 2016), and the ACT-America campaign (2015–2019; NASA, 2016). A few existing studies use these observations to attribute state-wide emissions. For example, Wecht et al. (2014b) use CalNex data to attribute state-wide \( \text{CH}_4 \) emissions from California.

Several satellites make total column observations of \( \text{CO}_2 \) and \( \text{CH}_4 \) (e.g., AIRS, TES, IASI, Envisat/SCIAMACHY, GOSAT, OCO-2, and GHGSat). Streets et al. (2013) describe a number of these satellites in detail, and Jacob et al. (2016) provide a thorough overview of \( \text{CH}_4 \)-observing satellites. Several of these satellites (Envisat/SCIAMACHY, GOSAT, OCO-2, and GHGSat) observe in the shortwave infrared. Relative to other satellites, these four are more sensitive to GHG mixing ratios in the lower troposphere and, hence, to emissions at the surface (e.g., Chevallier et al., 2005; Wecht et al., 2012). Only a handful of existing studies use these datasets to attribute sector-specific emissions in the US, and these studies focus on \( \text{CH}_4 \), not \( \text{CO}_2 \) (e.g., Schneising et al., 2014; Wecht et al., 2014a, b; Alexe et al., 2015; Turner et al., 2015). For example, Turner et al. (2015) use GOSAT observations to estimate sector-specific \( \text{CH}_4 \) emissions in North America and find results that are broadly consistent with emission estimates derived from the US tall-tower and aircraft monitoring network (Miller et al., 2013). Wecht et al. (2014b), however, explain that GOSAT observations are too sparse to constrain \( \text{CH}_4 \) emissions from California outside of the Los Angeles Basin.

4 Novel strategies that could be used for estimating sector-specific emissions

This section discusses two observational strategies that support top-down modeling efforts, strategies that show promise for estimating sector-specific emissions. First, we discuss the potential of upcoming and proposed satellite-based GHG observations. Next, we discuss the utility of “secondary tracers”. These gases or isotopologues are co-emitted with GHGs and aid in sector-specific attribution.

4.1 New satellite-based GHG observations

Existing satellites could hold enormous potential for estimating fossil fuel emissions. For example, several studies indicate that Envisat/SCIAMACHY and GOSAT should be able to constrain \( \text{CO}_2 \) emissions from large cities or large industrial regions (e.g., Schneising et al., 2008; Kort et al., 2012; Schneising et al., 2013). Kort et al. (2012) further argue that GOSAT could detect a trend as small as 22% from Los Angeles. OCO-2 and GHGSat should be even more capable. OCO-2 observations have a smaller footprint and precision relative to GOSAT. As a result, the satellite should be able to constrain \( \text{CO}_2 \) from large power plants (National Research Council, 2010). The privately funded GHGSat makes targeted observations over specific point sources with a smaller footprint than OCO-2 and should therefore be ideal for constraining large point sources (Kramer, 2017).

Other studies offer a more skeptical perspective on current satellite capabilities. Keppel-Aleks et al. (2013) argue that variations in total column \( \text{CO}_2 \) due to fossil fuel emissions are largely obscured by biospheric fluxes. Furthermore, Gavrilov and Timofeev (2015) find large biases (4.7 ± 2.6 ppm) in GOSAT retrievals of \( \text{CO}_2 \). Future retrieval improvements could reduce these biases (e.g., Dils et al.,
An additional challenge is that current satellites do not provide comprehensive global mapping and are therefore not well-suited for monitoring all urban areas and point sources (Fig. 2); Miller et al. (2007) point out that OCO-2 covers only 7–12% of Earth’s land surface. Trend detection can also be challenging. Individual satellites have limited lifetimes, and different satellite datasets with unique error characteristics and biases can be difficult to compare.

Future satellites, both selected and proposed, offer a number of improvements over existing capabilities. Some, like GOSAT-2 (selected), have better precision relative to the existing generation of satellites (Matsunaga et al., 2016). Other future satellites have a wide swath (CarbonSat, proposed) or are geostationary (GeoCARB and GEO-CAPE; selected and proposed, respectively). They would generate higher density observations across the US relative to OCO-2 and GOSAT (Fishman et al., 2012; Polonsky et al., 2014; Bovensmann et al., 2015; Buchwitz et al., 2013; Bousserez et al., 2016; Pillai et al., 2016). Lidar-based missions (e.g., MERLIN and ASCENDS; selected and proposed, respectively) measure in the absence of sunlight and through thin or scattered clouds (Kiemle et al., 2011; ASCENDS Ad Hoc Science Definition Team, 2015). As a result, these satellites would also generate dense observations relative to current satellites, particularly at high latitudes.

These future satellites should have sufficient precision and small footprints to constrain CO₂ emissions from power plants. They should also have better spatial coverage to monitor a greater number of emitters. For example, Bovensmann et al. (2010) report that the proposed CarbonSat satellite should be able to constrain CO₂ emissions from a mid-sized power plant to within 12–36%. Other studies, by contrast, indicate that future missions like ASCENDS would have difficulty constraining regional-scale fossil fuel CO₂ emissions from the US (ASCENDS Ad Hoc Science Definition Team, 2015) and would have limited ability to detect continental-scale changes in emissions (Hammerling et al., 2015). In addition to CO₂, future CH₄ observations also show promise. For example, the TROPOMI sensor is scheduled to launch in 2017. A year of observations should be sufficient to detect the largest 1% of grid cells in the EPA’s gridded CH₄ inventory (Maasakkers et al., 2016), equivalent to 30% of total national emissions (Jacob et al., 2016). Jacob et al. (2016) define emissions as detectable if the total column CH₄ enhancement is more than twice the sensor precision at aggregated timescales.

4.2 Secondary tracers

Secondary tracers are co-emitted with GHGs and are often emitted from only a small number of source sectors. These tracers make it possible to isolate and factor out at least a portion of natural fluxes or factor out emissions from source sectors that are not of primary interest. The top-down approaches discussed previously either require a limited geographic scope or accurate activity data to effectively estimate sector-specific emissions. Secondary tracers could identify sector-specific emissions without these limitations (though secondary tracers present challenges of their own). Examples of secondary tracers include radiocarbon (¹⁴C), ethane, ¹³CO₂, ¹³CH₄, and carbon monoxide (CO). We focus on radiocarbon and ethane because they hold particular promise.

4.2.1 Radiocarbon

Radiocarbon is produced by cosmic rays in the upper atmosphere and has a lifetime of approximately 5730 years before decaying back to ¹²C. Since the mid 1950s, nuclear bomb testing has elevated radiocarbon within the atmosphere (Bowman, 1990). CO₂ fluxes from the biosphere will mirror the isotopic composition of the atmosphere at the time that carbon was incorporated into the plant. CO₂ emissions from fossil fuels, by contrast, contain no radiocarbon because fossil fuel reservoirs are far older than the decay lifetime of radiocarbon, and these reservoirs have not interacted with atmospheric carbon during the intervening time period.

Several exploratory studies use radiocarbon to separate the atmospheric CO₂ signal from biogenic versus anthropogenic emissions. One study uses radiocarbon measurements from the US east coast to estimate the relative contribution of fossil fuel versus biogenic emissions (Miller et al., 2012). Another study reports on radiocarbon measurements in California (Riley et al., 2008). Graven et al. (2011) and LaFranchi et al. (2013) use radiocarbon observations from an aircraft and a tall tower, respectively, to estimate the contribution of anthropogenic and biogenic CO₂ emissions in Colorado. Beyond these studies, radiocarbon measurements are not widely used in regional- or continental-scale inversions.

Radiocarbon is not widely used, in part, because only a handful of atmospheric monitoring sites in the US report radiocarbon measurements. An expanded observation network shows enormous potential. NOAA and its partners currently measure radiocarbon in air samples from eight tall-tower sites, three mountaintop sites, and four aircraft sites in the US. NOAA collects these samples up to three times per week at tall-tower and mountaintop sites and collects up to two to three samples every 2 weeks at aircraft sites. Basu et al. (2016) explain that there were 1639 total radiocarbon measurements between July 2009 and April 2011 (21 total months). By contrast, the National Research Council (2010) recommends that the US invest USD 15–20 million annually to collect 5000–10 000 radiocarbon observations per year, but that goal has not yet come to fruition. Basu et al. (2016) argue that this level of investment would allow scientists to constrain US fossil fuel CO₂ emissions to within 1% per year and to within 5% per month.

Despite this promise, the use of atmospheric radiocarbon measurements also presents several challenges. One primary challenge is accounting for the disequilibrium effect (Bow-
man, 1990). The atmospheric abundance of radiocarbon has changed in the past 60 years due to nuclear bomb testing. CO$_2$ from decomposing organic matter (heterotrophic respiration) will reflect radiocarbon levels during the time that carbon was incorporated into plant tissue, not current atmospheric levels of radiocarbon. Furthermore, the lifetime of dissolved gases in the ocean is much longer than 60 years; thus, the isotopic signature of air–sea gas exchange will also lag the recent rise in atmospheric radiocarbon. One must account for this mismatch or disequilibrium when using radiocarbon measurements to partition between fossil fuel CO$_2$ and biospheric CO$_2$; biospheric (and ocean) fluxes will not necessarily match current atmospheric radiocarbon levels, but rather, they reflect the levels of a past date. Atmospheric sampling upwind of anthropogenic sources could be used to characterize the biospheric radiocarbon signature and would mitigate this concern.

### 4.2.2 Ethane

Methane is the primary component of natural gas, but natural gas also contains small quantities of other alkanes, including ethane. These trace constituents are collectively referred to as natural gas liquids. Oil and natural gas operations and biomass burning are the two primary sources of ethane to the atmosphere. Thus, enhancements in atmospheric ethane mixing ratios can indicate leaks from oil and gas infrastructure (e.g., Rudolph, 1995). Other CH$_4$ emitters, including agriculture, landfills, and wetlands, do not emit higher-order alkanes in substantial amounts. For example, Peischl et al. (2013) estimate that natural gas leaks account for 90 % of all ethane emissions in the Los Angeles metro region. If one has an estimate of ethane emissions and an estimate of the ethane content of natural gas, then one could estimate CH$_4$ emissions from oil and gas infrastructure. McKain et al. (2015), for example, measure CH$_4$ and ethane at several sites in Boston, and they use CH$_4$ / ethane ratios reported from natural gas pipeline operators to estimate the portion of Boston’s CH$_4$ emissions that are due to natural gas leaks. Several other studies similarly use ethane measurements to explore oil and gas industry emissions from Los Angeles (Wennerg et al., 2012), Dallas, Texas (Yacovitch et al., 2014), the Barnett Shale region (Smith et al., 2015; Townsend-Small et al., 2015), and from global oil and gas operations (e.g., Simpson et al., 2012; Schwietzke et al., 2014).

The use of ethane for CH$_4$ source attribution brings several challenges. Until recently, atmospheric observations of ethane were sparse. Research groups at the University of California, Irvine, and NOAA have measured ethane in air samples from global background sites since 1984 and 2004, respectively (Simpson et al., 2012; Helmig et al., 2016). Each group collects samples at 40–45 sites at weekly to seasonal frequencies. Recently, NOAA has expanded its ethane measurements to its US tall-tower and aircraft network. Instrumentation has also become more widely available with Aerodyne, Inc.’s ethane analyzer (Yacovitch et al., 2014).

The ethane content of natural gas can also vary by region and will change if natural gas liquids are removed at processing facilities (Fig. 3). These variations complicate the task of inferring CH$_4$ emissions using ethane measurements. Smith et al. (2015), for example, find three distinct ethane signatures in different areas of the Barnett Shale region. Townsend-Small et al. (2015) report that ethane content in the Barnett Shale region ranges from 6 % at natural gas wells to 13 % at oil wells.

In summary, secondary tracers like ethane and radiocarbon allow scientists to use measurement networks with broad spatial coverage (like those in Sect. 3.4) to estimate specific source sectors. These measurements bypass, to some degree,
the need to rely on the spatial and temporal patterns in an inventory for source attribution and the need to have accurate activity data to support inverse modeling. With that said, only some CO₂ and CH₄ source sectors have obvious secondary tracers, and the associated atmospheric observations are primarily collected by in situ networks, not by satellites. Furthermore, progress in this area has been limited because of measurement availability, but this limitation could change in the future with more funding (i.e., in the case of radiocarbon) or deployment of new instrument technology (i.e., in the case of ethane).

5 Synthesis discussion

In this section, we synthesize progress to date on estimating sector-specific CO₂ and CH₄ emissions at state and national scale. We also discuss forward-looking opportunities to improve sector-specific GHG emission estimates, with a particular focus on opportunities to integrate bottom-up and top-down strategies.

Recent innovations in both bottom-up and top-down efforts have advanced scientists’ abilities to identify emissions from specific source sectors. Several efforts have produced high-resolution, sector-specific inventory products that are based on more accurate, detailed activity data and EFs. These products are largely driven by research in academia and by the Joint Research Centre in Europe. New inverse modeling strategies can incorporate these inventory estimates in more rigorous ways that are not limited to the spatial patterns in the inventory. In addition, more extensive observations are available to support these inverse modeling efforts, observations that span a number of spatial scales. For example, numerous intensive measurement campaigns in the past 5 years have focused on large GHG-emitting regions, particularly cities and oil and gas production basins. The national US in situ network and remote sensing GHG observations have also expanded in the last decade, though the US in situ network expansion is smaller than the level required for robust evaluation of a wide array of GHG source sectors.

Despite these advances in bottom-up inventories, top-down strategies, and measurement density, the scientific community has only been able to use inverse modeling and atmospheric data to improve sector-specific emission estimates in a relatively small number of cases. To date, the community has had more success integrating top-down and bottom-up estimates for CH₄ than for CO₂; the atmospheric signal from biospheric CO₂ fluxes often obscures the signal from fossil fuel emissions, except in some urban environments. National CH₄ inventory estimates are often uncertain by a factor of 2–3 at the sector level, while CO₂ inventories typically agree to within 5% (Fig. 1). Arguably, the community has been able to use top-down inverse modeling to improve these inventories when they arguably stood to benefit most.

Specifically, the community has been most successful with top-down, sector-specific attribution in two types of scenarios: intensive measurement campaigns paired with local-scale inverse modeling and opportunistic cases. In the former case, the community has put substantial resources into intensive, local-scale measurement campaigns for a few specific source sectors. Measurements from each affected locality or region provide a puzzle piece, and the community has begun to assemble a cohesive, national-scale picture by amalgamating these individual pieces. The community has employed this strategy in the case of CH₄ emissions from oil and gas operations (e.g., the SENEX, SONGNEX, Barnett Coordinated Campaign) and, to a lesser degree, in the case of urban CO₂ emissions (including recent measurement efforts in Los Angeles, Salt Lake City, Boston, Indianapolis, and Oakland). These campaigns typically provide a snapshot of current emissions and would need to be repeated in the future to estimate how emissions vary over time.

Other cases of successful source attribution have been largely opportunistic. In certain cases, the community had the right atmospheric measurements and spatially distinct source sectors to attribute emissions at large spatial scales. For example, Miller et al. (2013) find large CH₄ emissions in Texas and Oklahoma that do not fit the spatial distribution of cows, and CH₄ measurements in that region correlate with measurements of higher-order alkanes. The authors conclude that a large fraction of those emissions are likely due to oil and gas operations. Turner et al. (2015) reach similar conclusions using satellite observations from GOSAT.

Numerous future opportunities would improve scientists’ ability to merge bottom-up inventories, inverse modeling, and atmospheric GHG data for better GHG source attribution:

5.1 Combine the strengths of existing datasets

Many inverse modeling studies to date use only in situ or satellite GHG data to estimate emissions. CH₄ inverse modeling studies for North America provide a good example. Miller et al. (2013) use in situ observations from long-term monitoring stations, Wecht et al. (2014a) use remote sensing observations from Envisat/SCIAMACHY, and Turner et al. (2015) use remote sensing observations from GOSAT. Future studies may be able to attribute emissions more effectively by leveraging the strengths of all available in situ and remote sensing datasets. Different datasets often bring complementary strengths for this attribution: remote sensing datasets have broad spatial coverage and in situ datasets have complete temporal coverage and greater sensitivity to surface emissions, among other strengths. A number of challenges may have prevented the synthesis of multiple datasets in past efforts: large datasets entail a number of computational challenges, the data are not always accessible, and the observations can have different information content or error characteristics that are challenging to balance in a single frame-
work. Future efforts that can combine these disparate datasets likely stand the best chance of attributing emissions to specific source sectors.

5.2 Expand several existing measurement strategies

Expanded GHG measurements would also advance efforts to attribute emissions to specific source sectors. As discussed earlier, some of the most successful top-down efforts to attribute emissions have been intensive aircraft campaigns. These campaigns are more flexible than the long-term monitoring network and can easily target source sectors of interest by flying in specific regions, in flight patterns that encapsulate the source of interest, and by flying at certain times of year that have fewer competing biogenic sources. An expansion of these campaigns would enable scientists to target specific source sectors, including CO₂ emissions from large power plants, CH₄ from agriculture, and CH₄ from coal mines, among other source sectors. These aircraft campaigns could then be used to estimate regional-scale EFs. Existing aircraft campaigns, for example, target CH₄ leakage rates for a range of different oil and gas drilling basins (see Sect. 3.1–3.2). The long-term in situ atmospheric network and GHG monitoring satellites could be used to intelligently extrapolate and gap-fill these regional EFs at larger spatial scales and to identify broad trends over time.

In addition, successful cases of sector-specific attribution have usually involved observations that span multiple spatial and temporal scales. This strategy allows scientists to bridge between the regional scale that atmospheric observations are best able to constrain and the facility-level scale where inventories are strongest. For example, atmospheric observations can be used to identify regional differences between top-down and bottom-up estimates. Subsequent facility-level and on-road measurements can indicate why those regional differences occurred and how to improve EFs in a way that will bring inventories into agreement with top-down estimates. This measurement strategy can be expensive and requires extensive coordination, but several studies employ it successfully in the case of oil and gas CH₄ emissions (e.g., Allen, 2014; Brandt et al., 2014; Peischl et al., 2015). Bottom-up and top-down estimates of these emissions disagree at regional and national spatial scales (e.g., Miller et al., 2013; Turner et al., 2015). Subsequent facility and on-road measurements elucidate why: a small number of malfunctioning facilities account for a large percentage of emissions. EFs that account for this skewed distribution are more consistent with regional top-down estimates (e.g., Brantley et al., 2014; Lavoie et al., 2015; Subramanian et al., 2015).

Effective source attribution will also likely require the use of secondary tracers. Measurements of some secondary tracers, like ethane, have expanded markedly in the past several years with advances in instrumentation. With that said, measurements of tracers like radiocarbon are only available for some of the long-term US monitoring sites.

5.3 Improve inverse modeling strategies with an eye toward secondary tracers

The inverse modeling community has yet to develop inverse modeling strategies that can fully leverage observations of secondary tracers. This task is not straightforward and would likely require the development of new strategies. These strategies would need to quantify heterogeneities in the ethane content of natural gas or the disequilibrium effect in the case of radiocarbon. Furthermore, these strategies may need to relate the primary and secondary tracers in a single statistical framework and account for uncertainties in that relationship. Observations of these secondary tracers have historically been very sparse, so few existing studies focus on designing statistical inverse modeling frameworks to fully exploit these tracers.

5.4 Develop detailed activity data as part of bottom-up efforts

Top-down efforts, like those outlined above, can help in developing regional-scale EFs for different source sectors. These studies can be particularly helpful when EFs are challenging to determine at facility scale. For example, direct measurements of oil and gas facilities are difficult to design because a small number of leaks account for the majority of emissions, and these large emitters may be difficult to find and/or representatively sample (see Sect. 2.3). In contrast to EFs, activity data can only come from bottom-up inventory efforts. In fact, top-down efforts depend upon reliable activity data for attributing emissions (Sect. 3.1 and 3.3). Efforts to improve these activity datasets would markedly improve source attribution. In many cases, these activity data exist but are not publicly available or are not available in gridded form. Gurney et al. (2007) cite local fuel sales or electric utility bills as examples. CH₄ emissions from oil and gas provide an additional example. Oil and gas wells generally report production figures to state regulatory agencies, but this reporting varies by state, does not have a consistent format, and can be difficult to find (e.g., http://pmc.ucsc.edu/~brodsky/wellindex.html). The inaccessibility of accurate activity data for oil and gas operations is a barrier to source attribution in recent national-scale CH₄ inverse modeling studies (Miller et al., 2013; Turner et al., 2015). Maasakkers et al. (2016) represents an important step forward in this area; the authors develop gridded versions of the EPA’s activity data. These activity data are key to connecting inverse modeling results with bottom-up estimates of specific source sectors. Future bottom-up efforts should particularly focus on the development and public release of gridded activity data.

In synthesis, future improvements in bottom-up inventories and top-down strategies would likely complement one another and translate into more reliable, sector-specific emission estimates; scientists will likely need to combine both
strategies to robustly estimate GHG emissions from individual sources. Improved activity data would lead to gridded inventory estimates with more accurate spatial and temporal patterns. Top-down frameworks could then harness these patterns, along with more extensive, future GHG observations, to estimate regional-scale EFs for specific source sectors. National-scale observations of secondary tracers like radiocarbon and ethane would further strengthen these top-down efforts for applicable source sectors. This coordinated, combined approach offers the most promising opportunity to evaluate state and national GHG emission reduction policies in the US.
