Abstract. An environmental scanning electron microscope (ESEM) was used for the first time to obtain well-resolved images, in both temporal and spatial dimensions, of lab-prepared frost flowers (FFs) under evaporation within the chamber temperature range from −5 to −18°C and pressures above 500 Pa. Our scanning shows temperature-dependent NaCl speciation: the brine covering the ice was observed at all conditions, whereas the NaCl crystals were formed at temperatures below −10°C as the brine oversaturation was achieved. Finger-like ice structures covered by the brine, with a diameter of several micrometres and length of tens to 100 µm, are exposed to the ambient air. The brine-covered fingers are highly flexible and cohesive. The exposure of the liquid brine on the micrometric fingers indicates a significant increase in the brine surface area compared to that of the flat ice surface at high temperatures; the NaCl crystals formed can become sites of heterogeneous reactivity at lower temperatures. There is no evidence that, without external forces, salty FFs could automatically fall apart to create a number of sub-particles at the scale of micrometres as the exposed brine fingers seem cohesive and hard to break in the middle. The fingers tend to combine together to form large spheres and then join back to the mother body, eventually forming a large chunk of salt after complete dehydration. The present microscopic observation rationalizes several previously unexplained observations, namely, that FFs are not a direct source of sea-salt aerosols and that saline ice crystals under evaporation could accelerate the heterogeneous reactions of bromine liberation.

1 Introduction

Ice and snow constitute an important reaction medium on Earth and are known to accumulate and concentrate significant amounts of impurities that are stored, transformed, and eventually released. The knowledge of the exact location and speciation of these chemical impurities in ice and snow under various environmental conditions is crucial for assessing their reactivity (McNeill et al., 2012; Bartels-Rausch et al., 2014; Gudipati et al., 2015) and further fate.

The ions originating from sea salt (including, for example, Na⁺, Cl⁻, and Br⁻) have been widely observed in polar regions in media such as aerosols, snow packs, and ice cores (DeAngelis et al., 1997; Rankin and Wolff, 2003; Fischer et al., 2007; Legrand et al., 2016). The sea salts trapped in snow packs form a large chemical reservoir and therefore embody a significant part of chemical reactions in the polar boundary layer (Abbatt et al., 2012). Conversely, inactive ions such as Na⁺ recorded in ice cores could serve as a palaeoclimate proxy for the past climate (Rankin and Wolff, 2003; Abram et al., 2013). Although the sea spray and bubble bursting in the open ocean surface dominate sea-salt aerosol (SSA) production on most of Earth, the winter SSA peaks observed at
most near-coastal sites in polar regions (Wagenbach et al., 1998; Rankin et al., 2004) are clearly out of phase with the distance to the open water. Several lines of evidence suggest that winter sea salt cannot derive only from the long-range transport of the aerosol produced over the open ocean. The winter maximum observed seems inconsistent with the fact that the nearest open water is hundreds of kilometres further away in the given season because of extended sea ice. In ice, significantly higher concentrations of salts are found in glacial periods, when sea ice was even more widespread and furthermore when relevant models do not suggest any greater transport (Mahowald et al., 2006). The most direct evidence of the salt that should originate from zones covered with sea ice arises from the composition of sea-salt aerosol and ice cores. Frequent episodes when the sulfate/sodium \([\text{SO}_4^{2-} / \text{Na}^+]\) ratio is below that of seawater, despite the addition of the non-sea-salt sulfate resulting from the oxidation of dimethylsulfide, are observed (Wagenbach et al., 1998). This is believed to occur due to the effect of mirabilite \((\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O})\) precipitating from the brine when the temperature drops below \(-6.4^\circ\text{C}\) (Wagenbach et al., 1998; Jourdain et al., 2008; Butler et al., 2016b; Marion et al., 1999), a segregation inapplicable to sea spray particles.

The sea ice microstructure is permeated by brine channels and pockets that contain concentrated seawater-derived brine. Cooling sea ice results in further formation of pure ice within these pockets as thermal equilibrium is attained, resulting in a smaller volume of increasingly concentrated residual brine (Light et al., 2003; Butler et al., 2016b). A fraction of such concentrated brine will be expelled upwards to form a thin layer of brine on the sea ice surface, where frost flower (FFs) can grow under a certain weather condition. The formation of mirabilite results in removing the major portion of the dissolved \(\text{SO}_4^{2-}\) from the brine, with less effect on the \(\text{Na}^+\) due to its large abundance compared to the sulfate (e.g. Butler et al., 2016b). The SSA produced from these residual brines consequently displays a depleted \([\text{SO}_4^{2-} / \text{Na}^+]\) ratio. However, for sea spray particles, the \(\text{Na}_2\text{SO}_4\) will not be fractionated in the atmosphere or the following deposition, even when these particles are exposed to sub-zero temperatures: the precipitated mirabilite remains within the body of the aerosol and has no effective pathway to escape.

FFs are commonly observed on fresh sea ice and preferentially grow on small-scale roughness nodules sticking above the surface or out of the brine, which is typically colder by 5 °C compared to bulk ice (Domine, 2005; Galley et al., 2015); at these conditions, the supersaturation of water vapour is frequently achieved (Style and Worster, 2009). Frost flowers often consist of feather-like dendritic ice crystal structures, and their surface can be covered by concentrated brine (Perovich and Richter-Menge, 1994; Barber et al., 2014; Galley et al., 2015). A detailed chemical composition analysis was performed, finding, inter alia, that FFs can reach the salinity of the concentrated brine of 120 practical salinity units (Douglas et al., 2012), which is in the effective range of the mirabilite precipitation (Butler et al., 2016b). FFs have the specific surface area of 185 (+80–50) cm² g⁻¹, measured by methane adsorption; such a specific surface area is about 5 times lower than that of freshly fallen snow. The surface area of FFs is estimated to be 1.4 m² per m² of ice surface (Domine, 2005). The fragile structure plus extremely high brine salinity (Rankin, 2002) make FFs the likely cause of chemical reactions (e.g. heterogenous, photochemical, and redox; Perovich and Richter-Menge, 1994; Kaleschke et al., 2004; Simpson et al., 2007) and source for SSA (Wagenbach et al., 1998; Wolff et al., 2003). However, recent studies propose that FFs are not as important as assumed previously (Obbard et al., 2009; Roscoe et al., 2011; Abbott et al., 2012). In particular, a recent wind tunnel experiment indicated that FFs are not a direct source of SSA (Roscoe et al., 2011). Apart from saline FFs, the snow lying on sea ice can be contaminated by seawater (or saline) through various pathways (Domine et al., 2004). These contaminated salty snows have been hypothesized to act as an efficient source of SSA (via blowing snow) and bromine (Yang et al., 2008; Legrand et al., 2016; Zhao et al., 2016; Levine et al., 2014). The relative importance of these two sea-ice-sourced SSA to the polar winter sea-salt budget is still under debate (e.g. Huang and Jaeglé, 2017; Xu et al., 2016; Rhodes et al., 2017). In any case (FFs or salty snow), the formation of SSA from salty ice particles requires its size to be reduced via the loss of water through either the evaporation or the sublimation processes, depending on the temperature. Until now, there was no detailed image at the microphysical scale to indicate what happens to saline ice under evaporation or sublimation. Moreover, current atmospheric chemical models consider the solutes’ impurities on ice to be present in a diluted liquid solution on the ice surface (Domine et al., 2013). Such a model is generally unsatisfactory in describing the real situation, and thus more realistic parameters for modelling are needed. Some of us previously showed that the concentration increase of nonpolar (Heger et al., 2011; Kania et al., 2014; Krausko et al., 2015a, b) and polar compounds (Heger et al., 2005, 2006; Heger and Klan, 2007; Krausková et al., 2016) can even lead to their crystallization under certain conditions.

In this study, we grew FFs in a laboratory and inspected them using an environmental scanning electron microscope (ESEM) to obtain some information about the state of impurities in/on the ice. The preparation of the FF samples to mimic the FFs naturally produced on sea ice is detailed in Sect. 2 together with the related information on the ESEM. The scanning results are presented in Sect. 3, the atmospheric implications are discussed in Sect. 4, and the conclusions are available in Sect. 5.

Figure 1. A frost flower (FF) grown in a polystyrene-isolated beaker in a walk-in cold room, at the temperature of $-30^\circ$C. Both pure water FFs and saline FFs were prepared for further microscopic scanning (see the text for details).

2 Methods

2.1 Growth of the frost flowers and preparation of the samples

The FFs were prepared in a custom-built 2 m $\times$ 2 m walk-in cold chamber. Inspired by the natural condition at which FFs grow (Style and Worster, 2009) and exploiting previous methods of preparation (Roscoe et al., 2011), we cooled the walk-in cold chamber down to $-30^\circ$C and inserted vessels containing pure water or an aqueous solution of NaCl (3.5 % w/w, similar to that of seawater) at 20$^\circ$C. The vessels were isolated with styrofoam to minimize the contact cooling of the solution by the floor of the walk-in chamber and to promote cooling by the air. We typically observed the following course of events: first, hoarfrost appeared on the sides of the beaker; then, an ice crust formed on the water level; subsequently, dendrite-shaped icy features (considered to be FFs) grew gradually, as shown in Fig. 1. After the ice reached a certain thickness, the FFs stopped growing and were collected into a pre-cooled vial to be stored at the temperature of liquid nitrogen. Care was taken to collect only the FFs from the ice surface, avoiding the hoarfrost condensed on the walls of the beaker. The FFs were fragile and fragmented during the manipulation. The FFs grown on the surface of pure water were powdery; however, those grown from the brine were sticky, and therefore two spatulas were needed to place them into the vials. We attempted to follow growth conditions similar to the natural ones; our sampling method guarantees that the features were grown on the ice surface, and thus the examined samples are believed to be very similar to natural FFs.

2.2 Environmental scanning electron microscope

The ESEM (AQUASEM II) is unique in the observation of nonconductive, wet, or liquid samples, with the specimen chamber pressure as high as 2000 Pa and temperatures ranging from 0 to $-30^\circ$C (Tihlarikova et al., 2013). The indicated temperature is measured on the sample holder. The temperature of the ice surface is estimated to differ by no more than 2$^\circ$C from that of the holder on which the temperature is measured. This estimate is based on the observation of the ice surface melting. The major source of the heat is the energy from the electrons used for scanning. The conditions inside the chamber allow for the observation of ice samples in conditions similar to those under which ice and snow occur naturally. No conductive coating of the sample is needed, because the positive ions resulting from the electron–gas ionization in high-gas-pressure conditions of the ESEM discharge the accumulated charge. The strength of this apparatus lies in the delicate control of the dynamic conditions in the specimen chamber via an originally designed hydration system enhanced with temperature and vapour flow control and an advanced cooling system integrated in the sample holder. The specimen chamber can be evacuated very slowly, with the possibility of reaching high-humidity conditions in the sample vicinity without purge–flood cycles (Neděla et al., 2015). The water vapour temperature is estimated to be around 10$^\circ$C. Care was taken to direct the steam away from the sample to prevent any heat-up. The regulation of the temperature in the vicinity of the sample allows us to study ice in precisely controlled conditions (Krausko et al., 2014). The temperature, pressure, and relative humidity in the chamber of the ESEM can be set close
The FFs were scanned at the chamber temperature of 3.1 FFs at a high temperature: brine fingers formation described previously (Maxa, 2011, 2016).

The flow speed was simulated as influenced by the shape of the sample, pumping speed, and through the detector’s aperture during the scanning of the sample. The flow speed varies from 2 m s\(^{-1}\) on the sample surface to 16 m s\(^{-1}\) at the distance of 0.7 mm above the sample surface (simulated for the experimental pressure of 300 Pa in the specimen chamber of the ESEM AQUASEM II and for the spherical shape of the sample). The flow is influenced by the shape of the sample, pumping speed, and ESEM aperture diameter. The flow speed was simulated as described previously (Maxa, 2011, 2016).

3 Results and discussions

3.1 FFs at a high temperature: brine fingers formation

The FFs were scanned at the chamber temperature of \(-5.2^\circ\text{C}\). Figure 3 shows many spikes sticking out from the main ice body; here, these will be referred to as fingers. The smooth texture is indicative of surfaces covered with a layer of a solution in contrast to the dry ice crystal surface observed

to the frost point to cause ice sublimation or gradual growth. The ESEM is equipped with a tungsten hairpin cathode as a source of electrons and also with two custom-built detectors (Neděla et al., 2011): an ionization detector for secondary electrons (surface sensitive to provide information about the morphology of the ice surface) and a highly material sensitive detector of backscattered electrons. A comparison of these two modes on identical samples yields complementary information on the morphology of the ice surface and ice grain boundaries contaminated by impurities.

As shown in Fig. 2, water vapour flows around the sample and through the detector’s aperture during the scanning of the sample. The flow speed varies from 2 m s\(^{-1}\) on the sample surface to 16 m s\(^{-1}\) at the distance of 0.7 mm above the sample surface (simulated for the experimental pressure of 300 Pa in the specimen chamber of the ESEM AQUASEM II and for the spherical shape of the sample). The flow is influenced by the shape of the sample, pumping speed, and ESEM aperture diameter. The flow speed was simulated as described previously (Maxa, 2011, 2016).

The relative humidity in our experiments was set to be slightly below the frost point, and therefore slow loss of the water from the sample could be observed. Thus, the micrographs obtained already at the beginning of the observations are not fully undisturbed; we assume that the water evaporates faster from the brine of a lower concentration compared to the more concentrated one (in accordance with Raoult’s law). The vapour pressures above the water, ice, and saturated brine (8.3 % \(w/w\)) at \(-5^\circ\text{C}\) are 422, 402, and 403 Pa, respectively. These values were calculated from the applied equations for the vapour pressure above the water and ice as adopted from Buck (1981); for the brine, the relevant formulae are proposed within the article by Perovich and Richter-

Figure 3. The dynamical in situ images of the formation of brine fingers during slow evaporation of water from the frost flower. The individual fingers bending and flapping around are highlighted in circles. The width of the seven indicated necks in Fig. 3f is measured as \(d_f = (2.23 \pm 0.43) \mu m\), mean \pm standard error of the mean. Imaged with the applied ESEM AQUASEM II; beam energy at 20 keV, ionization detector, water vapour pressure of 348 Pa, sample holder temperature of \(-5.2^\circ\text{C}\), and sample-to-aperture distance of 2 mm. Scale bar: 100 \(\mu\text{m}\). A video of this case is attached (S1).
An examination of the sequences of the micrographs suggested that the evaporation proceeds faster from the main ice body than from the fingers. This can be seen in the video of this case as the fingers exhibit a relatively stable shape even if the main ice body gradually abates. Thus, the concentration of the brine in the surface layer of the fingers is deemed to be higher than that on the main body. We can speculate that the higher concentration of NaCl on the fingers is a result of previous water vapour evaporation from the brine on the fingers. Possibly, the most concentrated solution is found on the tips of the fingers, where small spheres are sometimes formed. The increased local concentration of salt would effectively lower the water vapour evaporation rate, thus allowing further melting of the ice forming the fingers’ interior, thus not allowing its breakaway from the main body. For example, if the NaCl saturation concentration of 25% (w/w) is reached at −5.2 °C, the water partial pressure drops to 365 Pa from the 403 Pa at the brine equilibrium concentration (8.3%).

A particular consequence of a higher rate of water evaporation from the side wall of a finger and the main ice body compared to the fingertip is the formation and propagation of gulfs. This is well exemplified in Fig. 5, where the process resulted in the breakaway of large pieces of ice (>100 μm) from the mother body. First, a very deep gulf was formed which later separated the two pieces by a very thin neck, eventually leading to the breaking off of the two parts (Supplement S2). This case indicates that the evaporation or sublimation process indeed could cause a large ice particle to fall aside, but this phenomenon is not common, as we noticed it only once in all our observations (20 experiments). Moreover, there is no evidence that the brine fingers can fall apart to form a number of micrometre-sized particles.

The understanding of the structure of FFs is still far from complete. The 3-D X-ray micro computer tomography experiments suggest that salt impurities are present mostly on the ice surface (Hutterli et al., 2008). Such a finding is consistent with our observation and can be well understood, tak-
was larger. The widths of the four indicated necks measured are $d_1 = 0.87$, $d_{II} = 3.78$, $d_{III} = 26.30$, and $d_{IV} = 13.60 \mu m$. Scale bars: 200 $\mu m$. Figure 6b shows that the salt crystals can be found also on the protruding fingers. Microscopic conditions: ESEM AQUASEM II, ionization detector, air pressure of 520 Pa, sample holder temperature of $-17.0^\circ C$, and sample-to-aperture distance of 2 mm.

Figure 6. (a, b) The frost flower micrograph detailing the surface scattered by the NaCl crystals and the finger structures. Compared to the situation at a higher temperature (Figs. 3 and 4), the brine fingers looked stiffer, appeared more rarely, and the angle at the base was larger. The widths of the four indicated necks measured are $d_1 = 0.87$, $d_{II} = 3.78$, $d_{III} = 26.30$, and $d_{IV} = 13.60 \mu m$. Scale bars: 200 $\mu m$. Figure 6b shows that the salt crystals can be found also on the protruding fingers. Microscopic conditions: ESEM AQUASEM II, ionization detector, air pressure of 520 Pa, sample holder temperature of $-17.0^\circ C$, and sample-to-aperture distance of 2 mm.

3.2 FFs at a low temperature: NaCl crystal formation

The evaporation of FFs at the temperature of $-17^\circ C$ was also scanned, as shown in Figs. 6–9. Additionally to the liquid brine observed at $-5^\circ C$, we saw a large number of salt crystals widely spread on not only the ice surface layer but also the surfaces of the fingers (Fig. 6b). Apparently, as we observed the salt crystals, brine, and ice together at these conditions, the sample cannot be in the thermodynamic equilibrium (Fig. 4).

The fingers at $-17^\circ C$ were less numerous and more robust compared to those observed at higher temperatures, with their necks typically reaching tens of micrometres or more (Fig. 6). The flexibility of the fingers is demonstrated in Figs. 7 and S4 by the observation of thin neck tethering and eventual pulling back a large piece of ice to the main ice body. Together with our additional scanning performed at the temperatures of $-10$ and $-12^\circ C$ (not shown), we witnessed that chamber temperatures progressively decreasing below $-10^\circ C$ effectively increase the formation of crystals and reduce the number of fingers, indicating that the brine microphysical feature under sublimation or the evaporation process is temperature sensitive. Figure 8 clearly shows that salt crystals are widely formed on the surface brine layer during water evaporation from the FFs, eventually growing into a large cluster of crystals covering most of the surface. The dynamics of the process is shown by successive images joined into the video in S5. The size of the crystals varies from a few micrometres at an early stage to more than one hundred micrometres at a later stage. It is also possible to discern that salt crystals freely move on the brine surface, occasionally sinking below the surface. This can provide some indication of the thickness of the brine on the ice surface. It should be noted that, at the temperature of $-17^\circ C$, air with the relative humidity of ca. 20 % was always used instead of the pure water vapour applied at $-5^\circ C$, thus setting slightly evaporative conditions in the microscopic chamber.

We suppose that the sample heated up from the liquid nitrogen temperature to $-17^\circ C$ would allow the brine layer to approach the thermodynamic equilibrium concentration of 20 % ($w/w$). Referring to the mirabilite, fast dissolution of hydrohalite crystals is expected upon warming (Butler and Kennedy, 2015; Butler et al., 2016b); therefore, the observations are dependent on the temperature and pressure in the microscope’s chamber and not on the thermal history of the sample. Further water evaporation can easily cause the oversaturation of the brine solution to a concentration exceeding 24 % ($w/w$) and thus result in the consequent formation of salt crystals. Presumably, this occurs in our microscopic chamber at the above-indicated observation temperatures. We can exclude the assumption that the formed crystals are made of water ice as they grow (in size and number) during the evaporation process. The saturation can be reached via increasing the brine concentration by only 3 %, which can easily happen. This process is represented by the
Conversely, the shape of the most (but not all) of the salt crystals is close to rectangular, and therefore the cubic structure of halite can be inferred. The variety of NaCl crystal morphologies is presented in Fig. 9. It can be argued that, similarly to the non-thermodynamic homogeneous crystallization in aerosol chambers, halite preferentially crystallizes also in the conditions of our observation, for reasons we are currently unable to explain.

It is interesting to note that an anomalous increase of the water heat capacity with decreasing temperature is reduced and even eliminated with the increasing concentration of the NaCl in the solution. The isobaric heat capacity $c_p$ of 23 % brine at $-17.2 \, ^\circ C$ equals ca. 3.3 $\text{kJ} \, ^\circ \text{C}^{-1} \text{kg}^{-1}$ (Archer and Carter, 2000), which is substantially less compared to the $c_p$ of water at the same temperature (4.3 $\text{kJ} \, ^\circ \text{C}^{-1} \text{kg}^{-1}$). Conversely, the $c_p$ of ice (1.98 $\text{kJ} \, ^\circ \text{C}^{-1} \text{kg}^{-1}$ at $-17.2 \, ^\circ C$) is still much lower than that of water or brine (Haida et al., 1974). Therefore, at thermal gradients, ice will change its temperature faster than the liquid parts of the system.

### 4 Atmospheric implications

Although our laboratory-prepared FFs can be regarded as one particular example of the natural FF, we cannot determine how representative this example is, especially as the FF’s interior structure has not been detailed yet. However, we can consider our observations a good model for the general case of sea ice, with the limitation to the ice–NaCl system. It should be stressed that Na$^+$ and Cl$^-$ comprise 85.7 % of the total salt in seawater by mass (Millero et al., 2008). The remaining 14.3 % of solutes may play an important role in the geochemistry of FFs and thus may be important for certain considerations. In particular, the precipitated ikaite and mirabilite from seawater, at $-2$ and $-6.4 \, ^\circ C$, respectively, may possibly act as nucleation centres for NaCl (Butler et al., 2016a). Obviously, the omission of other salts in this study is a limitation to representing real FFs. We should also stress that our observations were performed at the chamber pressure of $p \approx 600 \, \text{Pa}$, which is substantially lower compared to low atmospheric conditions; therefore, direct implications for the natural FF should be made with care and questioned in further work. Nevertheless, our observations reveal some possibly relevant facts, and these are outlined below.

#### 4.1 In atmospheric chemistry

Exposing a progressively concentrated brine to the ambient air, following the evaporation of water, may have a significant atmospheric implication, especially in atmospheric chemistry. Depending on the original position of the brine, namely, if it was located on the ice surface or buried in-between the ice crystals in the vein channels and pockets, the evaporation of the surrounding ice may increase the brine surface area by several times or even more than an order of magnitude. This could potentially accelerate the heterogeneous processes.
reactions; one particularly important reaction is bromide liberation, $\text{HOBr}(g) + \text{Br}^- \rightarrow \text{Br}_2(g)$, which is believed to be the direct source of bromine from the saline particles in polar regions (Fan and Jacob, 1992).

As reflected in the images taken, the exposed brine fingers may tangle together and combine with the mother body to form a large chunk of salt in the end (Fig. S3). Therefore, the increase in the surface area of the brine due to the exposure of the brine fingers to the ambient air could only be efficient during the evaporating period as aged FFs may exhibit a reduced area due to the formation of a precipitate. Thus, the acceleration of heterogeneous chemistry due to the evaporation process likely applies to fresh FFs and salty snows but not aged ones.

Compared to the crystals lying on the sea ice surface, those aloft snow particles may be more prone to losing their water (Mann et al., 2000). Therefore, salty blowing snow particles lofted from the surface may suffer from rapid loss of water and enhanced bromide liberation, as reflected in recent measurements (Jacobi et al., 2012; Lieb-Lappen and Obbard, 2015). Note that the effects of air ventilation in snow packs on snow chemistry, via the abovementioned sublimation process, remain unknown to date and thus deserve further in situ measurement.

Even though atmospheric conditions on Earth do not often allow for the formation of hydrohalite from bulk brine or in aerosols (Koop et al., 2000; Cziczo and Abbatt, 2000; Wagner and Mohler, 2013), we demonstrate that the local concentration on ice covered with brine exposed to desiccation by wind ventilation can easily meet these conditions. In the real world, an extremely dry conditions is not common in most sea-ice-covered zones; however, the wind ventilation effect could also cause ice water loss even under a high-relative-humidity condition (Thorpe and Mason, 1966). The ventilation effect is efficient and could dominate the water loss in the chamber even when the relative humidity is close to 100 %. Under the Earth’s atmospheric conditions, it could be possible that the ventilation effect is strong enough to trigger NaCl crystal formation. However, anhydrous crystals are not easily prevented from deliquescing; most likely, these crystals will be soon diluted to form brine again. From the general point of view, the impact of the temperature and ventilation effects on saline brine microphysical features, as observed in this study, is interesting and may have significant implications for atmospheric chemistry and climate, for example, with respect to ice nucleation (Wagner and Mohler, 2013).

The sea-salt aerosol produced from saline particles could effectively form a large reservoir of various chemical compounds. Moreover, these aloft SSA could easily become chemically active once they are airborne; they can get acidified quickly by absorbing naturally generated or anthropogenic sulfate or nitrate gases, which is a key step for bromide liberation from saline particles (Abbatt et al., 2012). The models integrating these airborne SSA as a source of bromine can aptly capture the observed bromine explosion and ozone depletion events often occurring in polar spring time (Yang et al., 2010; Legrand et al., 2016; Zhao et al., 2016; Theys et al., 2011).
4.2 In sea-salt aerosol formation

It seems that, without external forces such as collisions or wind cropping, evaporation itself will not automatically cause particle splitting to form sub-particles. The sticky brine fingers tend to combine back to the mother body (as shown in Fig. 7) rather than to fly away to form sub-particles. The leftover of FFs’ evaporation is normally a large chunk of salt, as shown in Fig. S3. Thus, the present study supplies a clear microphysical picture in the explanation of why FFs could not be a direct source of SSAs, which is in accordance with the observation by Roscoe et al. (2011) that no SSAs were detected at wind tunnel speeds up to 12 m s\(^{-1}\). Blowing snow on sea ice, as hypothesized by Yang et al. (2008), can produce SSA through a sublimation process. Recent modelling studies have shown that this process could reproduce well the polar winter SSA peaks in most polar sites (Levine et al., 2014; Huang and Jaeglé, 2017; Rhodes et al., 2017). As indicated in the present study, FFs are ruled out as a direct source of SSA, thus making blown salty snow particles more likely to be an efficient SSA source, as suggested previously.

Regarding less-salty snow particles, it is not clear whether the sublimation process will cause splitting. There is always a potential for large snow particles, e.g. ones with the size of hundreds of micrometres, to split during the evaporation process, especially when the surface brine skim is discontinuous. However, for much smaller particles (tens of micrometres or less), the splitting is less likely compared to the larger ones.

Although the results of this study indicate that the ratio (of the number of SSAs formed from one snow particle) could be close to 1, the dependences of the ratio on the particle initial size and salt content are not known. In the original formula for the parameterization of SSA production from blown snow (Yang et al., 2008), the ratio is assumed to be a unit; however, a large ratio of 5 was applied in a recent model integration (Huang and Jaeglé, 2017).

5 Conclusions

An ESEM was used, for the first time, to obtain a detailed microphysical picture of evaporating frost flowers prepared from NaCl solution. The thorough scanning, in both temporal and spatial dimensions reveals a secret world of FFs in their evaporation period.

The evaporation of water from the brine causes ice melting underneath as it supplies the melting water to dilute the locally increased salt concentration. This process results in the formation of naked fingers standing out of the main body of the FFs. These fingers covered with the concentrated brine supply an enhanced surface area where (heterogeneous) reactions, exemplified by bromide release, could be boosted. Whether this microphysical picture, taken for saline FFs in this study, applies also to less-saline snowpacks on sea ice and to blown salty snow particles, requires further investigation.

The exposed brine fingers are rather sticky and flexible at a higher temperature (e.g. \(-5^\circ\mathrm{C}\)); they, however, become stiff with the temperature dropping due to a lower amount of liquid in the brine. A multitude of micrometric NaCl crystals were observed in the brine layer at temperatures below \(-10^\circ\mathrm{C}\), indicating that the brine’s microphysical feature is temperature sensitive, thus changing the physical and optical properties of the FFs. As a newly discovered aspect, the presence of NaCl crystals should be considered with respect to possible atmospheric heterogeneous reactivity and the distribution of ions in bulk ice.

It is very likely that, without external forces, the evaporation process itself will not automatically cause a saline crystal to fall apart to produce aerosol size particles. The sticky brine fingers tend to tangle each other and eventually unite with the main body instead of forming multi-sub-particles, indicating that FFs are not a direct source of SSA, which is consistent with previous suggestions (Roscoe et al., 2011). This technique allows us to observe liquid NaCl brine on the ice surface and the process of its evaporation.
