Abstract. Cooking emissions can be a significant source of fine particulate matter in urban areas. In this study the aerosol- and gas-phase emissions from meat charbroiling were characterized. Greek souvlakia with pork were cooked using a commercial charbroiler and a fraction of the emissions were introduced into a smog chamber where after a characterization phase they were exposed to UV illumination and oxidants. The particulate and gas phases were characterized by a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) and a proton-transfer-reaction mass spectrometer (PTR-MS) correspondingly. More than 99 % of the aerosol emitted was composed of organic compounds, while black carbon (BC) contributed 0.3 % and the inorganic species less than 0.5 % of the total aerosol mass. The initial O : C ratio was approximately 0.09 and increased up to 0.30 after a few hours of chemical aging (exposures of 10^{10} molecules cm^{-3} s for OH and 100 ppbh for ozone). The initial and aged AMS spectra differed considerably ($\theta = 27^\circ$). Ambient measurements were also conducted during Fat Thursday in Patras, Greece, when traditionally meat is charbroiled everywhere in the city. Positive matrix factorization (PMF) revealed that cooking organic aerosol (COA) reached up to 85 % of the total OA from 10:00 to 12:00 LST that day. The ambient COA factor in two major Greek cities had a mass spectrum during spring and summer similar to the aged meat charbroiling emissions. In contrast, the ambient COA factor during winter resembled strongly the fresh laboratory meat charbroiling emissions.

1 Introduction

Organic aerosol (OA) is one of the main components of atmospheric particulate matter (PM) (Kanakidou et al., 2005; Zhang et al., 2007). Identification of the sources of OA has proven to be a difficult task due to their diversity and the continuous chemical evolution of the corresponding organic compounds. The aerosol mass spectrometer (AMS, Aerodyne Research) provides continuous information (OA mass spectra) that allows the identification of some OA sources. Additionally, the OA elemental ratios (O : C, H : C, N : C) can be calculated providing useful information about the average chemical state of the OA (Aiken et al., 2008). Positive matrix factorization (PMF) (Paatero and Tapper, 1994; Lanz et al., 2007) is often used to deconvolute the AMS data into a linear combination of factors. The resulting OA factors are associated with primary OA (POA), such as the hydrocarbon-like organic aerosol (HOA) or oxidized OA (OOA), which in many cases is related to secondary OA (SOA) (Zhang et al., 2007). Factors linked to biomass burning emissions (BBOA), cooking organic aerosol (COA), and marine emissions (MOA) have also been identified. The OOA has been further separated into factors based on their degree of oxidation and volatility (Zhang et al., 2007; Kostenidou et al., 2009, 2015; Sun et al., 2011; Ge et al., 2012; Mohr et al., 2012; Crippa et al., 2013a, b).

COA has been found to represent 10–35 % of the total OA measured in urban locations (Allan et al., 2010; Sun et al., 2011, 2012; Ge et al., 2012; Mohr et al., 2012; Crippa et al., 2013a, b; Lee et al., 2015). In Greece the COA levels

have been estimated in two major cities: Athens and Patras. During the summer the COA-related source (named HOA-2) was 17 and 14 % of the total OA in Athens and Patras, respectively (Kostenidou et al., 2015). For the winter the corresponding contributions were 16 % for Athens and 12 % for Patras (Florou et al., 2017).

Emissions from meat cooking may produce large amounts of aerosol up to 40 g kg^{-1} (Hildemann et al., 1991). The types of meat cooked (chicken, beef, etc.), other food ingredients, and the cooking method affect both the aerosol emission rate and the composition of the corresponding particles (Rogge et al., 1991; Mohr et al., 2009; He et al., 2010). For example, Allan et al. (2010) suggested that the oil used during meat frying may contribute more to the emitted PM than the meat itself in urban areas in the United Kingdom.

Meat cooking particles contain palmitic acid, stearic acid, oleic acid, nonanal, 2-octadecanal, 2-octadecanol, and cholesterol (Rogge et al., 1991). Schauer et al. (2002) measured the emissions from cooking with seed oils, showing that this process is a source of *n*-alkanoic and *n*-alkenoic acids. Allan et al. (2010) reported AMS spectra for several oils used for cooking, showing similar spectra (with enhanced fractions of signal at m/z 41 and 55) with some COA factors reported in the literature.

Most of the AMS spectra from ambient measurements related to COA are characterized by peaks at m/z values 41, 43, 55, 57, 69, etc. and have an O : C ratio ranging from 0.08 to 0.21 (Mohr et al., 2009, 2012; Allan et al., 2010; He et al., 2010; Sun et al., 2011, 2012; Ge et al., 2012; Crippa et al., 2013a, b; Hayes et al., 2013). He et al. (2010) reported coefficients of determination (R^2) of 0.95–0.98 among the spectra of OA emissions from different types of Chinese cooking despite the differences in ingredients and cooking methods. Mohr et al. (2009) compared the spectra of OA produced by grilling of hamburgers and chicken without skin. R^2 values greater than 0.9 were found between these AMS spectra. Mobile aerosol measurements indicate that commercial and residential cooking contribute to enhanced OA concentrations (Elser et al., 2016).

Despite the previous efforts, there are a number of remaining questions regarding the characterization of the emissions related to cooking practices. Separation of COA from the HOA and other primary components is still a challenge for the PMF analysis (Mohr et al., 2009; Kostenidou et al., 2015). Ots et al. (2016) attempted to constrain COA emissions in the UK using the AMS-PMF results. Furthermore, the fate of these primary emissions in the atmosphere is still unknown. The reactions with ozone (O_3) and OH radicals may significantly alter these aerosols. Hearn et al. (2005) studied the reaction of oleic acid particles with ozone and concluded that relatively fast heterogeneous reactions occur at the surface of the particles. Dall'Osto et al. (2015) reported different COA factors for a rural site in the Po Valley, Italy, with one being associated partially with primary organic aerosol components such as HOA and partially with sec-

ondary components. In contrast, the second COA factor did not correlate with primary tracers. Kostenidou et al. (2015) reported an HOA-2 factor for the summer measurements in Athens and Patras, Greece, that appeared to be associated with cooking but was quite different from the COA factor identified in winter in the same areas by Florou et al. (2017). The reasons for the differences of the COA factor spectra even when the cooking practices are the same in the two seasons were not clear. Due to the mild climate in Greece, there is no significant change in what is cooked during the different seasons as opposed for example to cities in much colder climates.

The aim of this work is to characterize the particulate emissions of pork charbroiling, an activity that is thought to produce large amounts of OA. Smog chamber experiments were conducted in order to characterize the fresh and aged meat charbroiling emissions. The resulting spectra were compared to COA factors derived from ambient measurements in Greece during different periods of the year in an effort to explain the apparent differences in COA spectra derived from the PMF analysis.

2 Experimental procedures

2.1 Chamber experiments

A set of five smog chamber experiments were conducted in the ICE-HT environmental chamber facility. This facility is composed of a temperature-controlled smog chamber room ($3 \text{ m W} \times 4.5 \text{ m L} \times 2.5 \text{ m H}$) incorporating over 300 UV light lamps (Osram, L36W/73) capable of producing a J_{NO_2} of 0.6 min^{-1} (when all lights are turned on). The reactor had a volume of 10 m^3 . A commercial charbroiler was used for the meat cooking. Natural wood coal was purchased from local distributors. A butane burner was used for the ignition of the coal. The charbroiler was placed outside the laboratory and adequate time was allowed for the coal ignition. Pork was purchased from the local market. The meat was cut into $2 \times 2 \times 1 \text{ cm}$ pieces which were placed on wood sticks (length: 20 cm). Approximately 100 g of meat were used for each souvlaki. This type of cooking is widely used in Greece, both in restaurants and homes. Ten to 15 souvlakia were cooked for approximately 20 min. Using a metal bellows pump (Senior Aerospace, model MB 602) a fraction of the emissions was introduced into the 10 m^3 Teflon (PTFE) chamber that had been pre-filled with clean air. Insulated 0.375 in. copper tubing (less than 2.5 m in length) was used to transfer the cooking emissions into the chamber. The copper tubing used for the sampling was insulated and was therefore heated by the exhaust vapors. We have confirmed that the metal bellows pump, as expected based on its design, does not generate particles or volatile organic compounds (VOCs). The PM_{10} losses in this pump have been characterized previously (Kostenidou et al., 2013) using two scanning mobility par-

Table 1. Summary of smog chamber experiments.

Chamber exp. ¹	Initial PM ₁ concentration (μg m ⁻³)	Aging procedure	Initial O : C	Initial H : C	Final O : C	Final H : C	Average OH (molec cm ⁻³)	O ₃ formed (ppb)	θ angle initial vs. final

¹ The total duration of experiments 1–4 was 7–8 h and that of Experiment 5 was 4.5 h.

² In Experiment 1 no d-butanol was added, and thus no OH radical concentration is reported.

ticle sizer (SMPS) systems for both ammonium sulfate and ambient particles. The losses were less than 10 % for particles larger than 150 nm, increasing to 30 % for 100 nm particles. The flow rate for the transfer line was approximately 170 L min⁻¹. The temperature and relative humidity were in the range of 20–25 °C and 15–35 %, respectively. Air was sampled 1 m above the charbroiler for approximately 10 min in order to achieve a concentration inside the chamber of the order of 100–500 μg m⁻³. The conditions of each experiment are shown in Table 1. The NO_x concentrations were in the range from 1.5 to 8 ppb. The NO₂-to-NO ratio ranged from 2 to above 10. The NO_x analyzer used is sensitive to other NO_y compounds and thus its measurements represent an upper limit of NO₂.

A high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS, Aerodyne Research Inc.) measured the non-refractory PM₁ aerosol. The vaporizer temperature was set at 600 °C and the voltage difference between the filament and the ion chamber was 70 V. The V mode of the AMS was used in these experiments. A SMPS (classifier model 3080, DMA model 3081, CPC model 3787, TSI) measured the particulate number size distribution. The sheath flow rate was 5 L min⁻¹ and the sample flow rate was 1 L min⁻¹. The size range of the SMPS under this configuration is from 10 to 500 nm. The 10 : 1 ratio provides more accurate size distribution measurements as the instrument has a sharper transfer function but it reduces the measurement range to 10–300 nm. Given the modest size accuracy requirements in this study (a few percent), we selected to cover a larger size range instead. A multiple-angle absorption photometer (MAAP, Thermo Scientific Inc.) was used for the measurement of the PM₁ particulate black carbon (BC).

Quartz filters, placed after a PM_{2.5} cyclone, were used to collect samples of the emitted COA from directly above the charbroiler and from inside the chamber at the end of selected experiments. These samples were used for the measurement of the organic (OC) and elemental carbon (EC) by thermal – optical analysis (Sunset Laboratory Inc., EUSAAR 2 protocol) and for the analysis of the water-soluble organic carbon (WSOC). For the WSOC extraction a *P* parameter value

equal to 0.1 cm³ m⁻³ was used according to Psichoudaki and Pandis (2013). The *P* parameter expresses the ratio of the water used for the extraction of WSOC per volume of air sampled on the filter to be analyzed. Samples were collected on Teflon (PTFE) filters in one experiment in order to estimate the particulate mass emission factor from the charbroiling of pork. Air was sampled from the charbroiler (just above the pork) at a rate of 225 L min⁻¹ through a custom-built exhaust line (100 mm id). A portion of these emissions were sampled through a 0.375 in. line after passing through a PM_{2.5} cyclone at 4 L min⁻¹. Known portions (25 g) of pork were individually cooked until well done and the emissions generated were sampled from the exhaust line.

The VOCs were measured by a proton-transfer-reaction mass spectrometer (PTR-MS, Ionicon Analytik). The drift tube was operated at 600 V at a constant pressure of 2.2–2.3 mbar. The flow rate was 0.5 L min⁻¹. Further information about the PTR-MS operation can be found in Kaltsonoudis et al. (2016). Blank measurements were conducted prior to the introduction of meat cooking emissions to the chamber in each experiment. A series of gas monitors was used for the measurement of the mixing ratios of the nitrogen oxides (NO_x), ozone (O₃), carbon monoxide (CO), and carbon dioxide (CO₂) (Teledyne models: T201, 400E, 300E, and T360, respectively).

Aging experiments were conducted in order to simulate the evolution of the freshly produced COA as it reacts with typical oxidants (O₃ and OH) in the atmosphere. UV illumination was used ($J_{\text{NO}_2} = 0.59 \text{ min}^{-1}$) and the chemical evolution of the particulate and gas species was monitored. In some experiments, ozone was added and the ozonolysis of cooking emissions in the dark was investigated (Table 1). No OH precursor was used in any of the experiments.

2.2 Ambient measurements

Ambient aerosol was sampled at the ICE-HT institute (8 km NE from the center of Patras) during February 2012 (Kostenidou et al., 2013). This period included Fat Thursday (16 February) during which meat is charbroiled everywhere in Patras. The instrumentation used for the ambient mea-

surements is described in Kostenidou et al. (2013). Briefly, an HR-ToF-AMS was deployed for the characterization of the non-refractory PM₁ aerosol composition, a PTR-MS was used for the VOCs, an SMPS for the size distributions, a MAAP for the BC, and a series of gas monitors were used for the NO_x, O₃, CO, and CO₂ concentrations. All instruments sampled from approximately 4 m above ground. A PM_{2.5} cyclone was used in front of the MAAP.

2.3 Data analysis

For the HR-AMS data analysis, SQUIRREL v1.56D and PIKA v1.15D with Igor Pro 6.34A (Wavemetrics) were used, applying the fragmentation table of Aiken et al. (2008). The O:C and H:C ratios were estimated using the improved method of Canagaratna et al. (2015). High-resolution PMF analysis (Paatero and Tapper, 1994; Lanz et al., 2007) was performed using the HR-AMS data from the chamber experiments and the ambient measurements. The PMF evaluation tool PET (Ulbrich et al., 2009) was used for both cases. The Multilinear Engine (ME-2) through Source Finder software (SoFi) (Canonaco et al., 2013) was also used for the analysis of the ambient measurements to investigate the robustness of the corresponding results of the PMF. In all cases we used the m/z of 12–200 at high resolution as inputs.

The OH radical concentrations were estimated using isotopically labeled butanol (1-butanol-d9, Sigma). The change of the concentration of the PTR-MS m/z 66 was used to calculate the OH concentrations based on the second-order reaction of d9-butanol with the OH radicals. The corresponding reaction constant used is $3.4 \times 10^{12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Barnet et al., 2012). The wall losses corrections for the particles inside the chamber were calculated according to Pathak et al. (2007) assuming a first-order loss rate for the mass concentration of the total OA. The loss rate constant was established during the characterization period of each experiment prior to the beginning of chemical aging. The wall rate constants obtained for the experiments were in the range of 0.14–0.28 h⁻¹ and the corresponding linear fits had very high correlation coefficients. Losses of particles to the walls do remove part of the OA from the air in the chamber and make it “invisible” for our measurements. However, the observed chemical changes were relatively fast, taking place mostly within a couple of hours. The corresponding timescales for losses were 4–6 h, so our conclusions are quite robust. This can be clearly seen, for example, in the dark ozonolysis experiment where fresh COA is decreasing following the O₃ addition significantly faster than it is lost to the walls before aging begun. However, the fact that we could not observe the corresponding potential changes to the COA particles deposited on the walls introduces some uncertainty in the results. While one would expect similar changes in these deposited particles if mass transfer of oxidants and condensable material was rapid enough, we cannot confirm this. However, the effect of wall losses of particles on the observed

Table 2. Composition (% mass) of the freshly emitted COA for the laboratory experiments.

	Experiment					Average
	1	2	3	4	5	
Organics	98.4	99.0	99.4	99.4	99.6	99.2 ± 0.5
Sulfate	0.1	0.5	0.1	0.1	0.1	0.1 ± 0.2
Ammonium	0.0	0.0	0.0	0.0	0.0	0.0 ± 0.0
Chloride	0.5	0.0	0.1	0.1	0.1	0.2 ± 0.2
Nitrate	0.2	0.1	0.2	0.3	0.2	0.2 ± 0.1
BC	0.8	0.4	0.2	0.2	0.1	0.3 ± 0.3

SOA/POA ratio is expected to be from modest to small. This has also been addressed by the work of Hildebrandt et al. (2009), who discussed the extremes of the potential fate of particles deposited on smog chamber walls.

3 Source characterization experiments

3.1 Size distribution and chemical composition of the fresh COA

Table 2 summarizes the composition of the fresh cooking aerosol for the five chamber experiments. The emitted aerosol is dominated by organic compounds (above 99 %) in all experiments. BC was on average only 0.3 % of the PM₁. This is consistent with the OC and EC filter analysis of the PM_{2.5} aerosol that was sampled directly from the charbroiler. In these samples, the EC content for the fresh cooking emissions was less than 0.6 % of the total carbon. McDonald et al. (2003) reported that EC emissions from charbroiling and grilling of chicken and beef were 0.3–2.7 % of the total mass using charbroilers fueled by natural gas. Li et al. (2015) also reported low EC emissions due to cooking in China (1.8–10.7 % for meat roasting, 7.5 % for fish roasting, 6 % for street snack broiling, 1.9 % for cafeteria frying, and 10.7 % for cafeteria broiling). In that study the WSOC-to-OC ratio was 0.05–0.15, indicating that the freshly emitted aerosol was mostly hydrophobic.

Figure 1a depicts the average HR-AMS mass spectra for the fresh meat charbroiling emissions. The initial spectra in all five experiments were similar with each other having angles θ of 0–7° (R^2 ranging from 0.983 to 0.999). The comparison of the AMS spectra based on θ angles was favored for the analysis of the results in the present paper. Briefly, a θ of 0–5° shows an excellent match between the two spectra (with an R^2 ranging approximately from 1 to 0.99), a θ of 6–10° shows a good match (with an R^2 ranging approximately from 0.98 to 0.96), a θ of 11–15° shows that the two spectra have many similarities but they are not quite the same (with an R^2 ranging approximately from 0.95 to 0.92), and finally a θ from 16 to 30° indicates spectra from different sources though there is some limited similarity (R^2

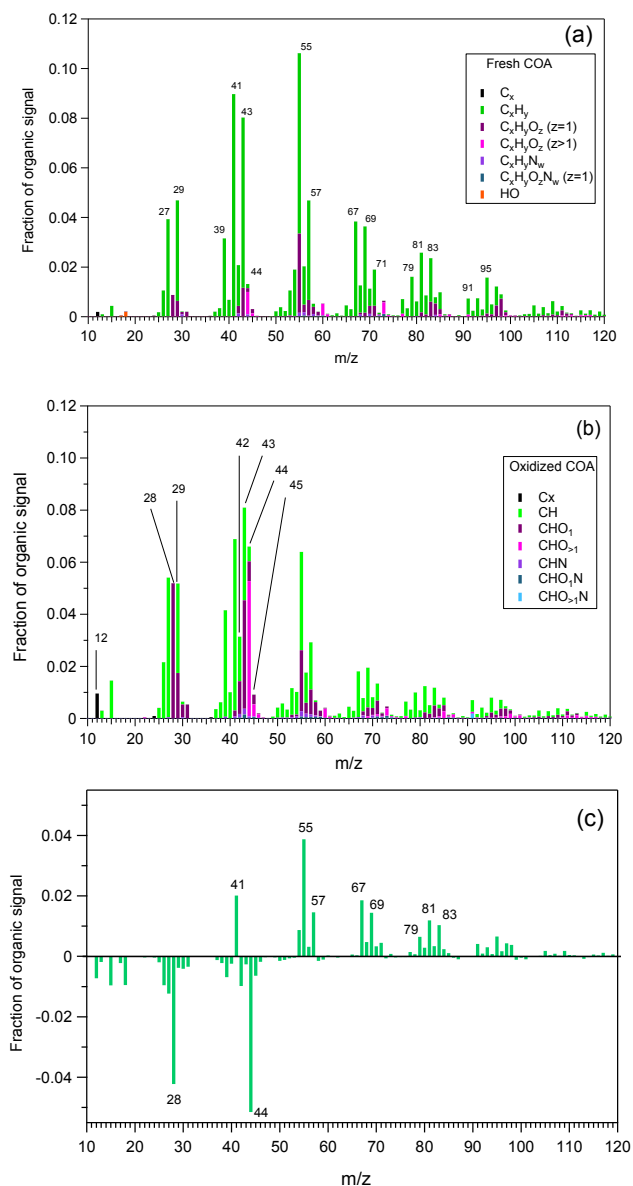

Figure 1. (a) Fresh COA mass spectrum, (b) aged COA mass spectrum for Experiment 2 (8 h of UV), and (c) the difference between the fresh and aged COA.

ranging approximately from 0.91 to 0.73). Values of θ higher than 30° suggest clearly different spectra. The advantage of the θ angle use for mass spectra comparisons is that it can represent better small differences than the R^2 coefficient. For example, small differences of $1\text{--}5^\circ$ all correspond to $R^2 = 0.99$. The initial O : C and H : C ratios based on Canagaratna et al. (2015) and based on Aiken et al. (2008) in parenthesis were on average 0.10 ± 0.01 (0.08 ± 0.01) and 1.94 ± 0.03 (1.80 ± 0.03), respectively. The main peaks of the corresponding AMS spectra were at m/z values 27, 29, 39, 41, 43, 55, 57, 67, 69, 71, 79, 81, 83, 91, and 95. The majority of these fragments correspond to homologous chains free

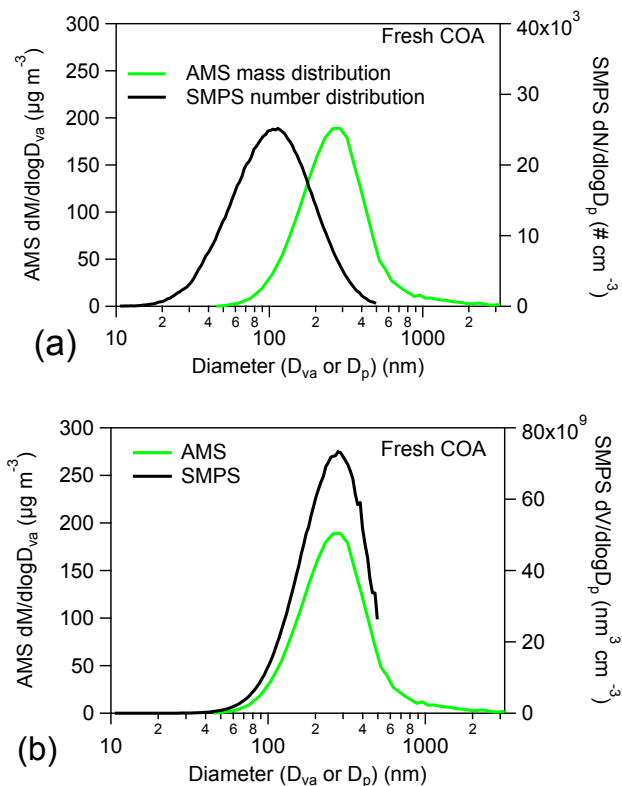

Figure 2. (a) SMPS number and AMS mass distributions versus D_p and D_{va} correspondingly for fresh COA and (b) SMPS volume and AMS mass distributions versus D_{va} and D_p .

of oxygen. The gas-phase CO_2 contribution to the CO_2^+ signal was corrected by sampling through a HEPA filter during the experiments. The CO_2 levels were in the 395–435 ppm range and did not change significantly during the course of each experiment.

The number-mode mobility diameter (D_p) of the fresh COA measured by the SMPS was 86 ± 20 nm, while the mass-mode vacuum aerodynamic diameter (D_{va}) measured by the AMS was 224 ± 30 nm. Figure 2a shows the fresh COA number and mass distributions versus D_p and D_{va} correspondingly for Experiment 1. Figure 2b shows the mass and volume distributions versus D_{va} and D_p correspondingly for the fresh COA in the same experiment. The AMS and the SMPS estimated aerosol mass concentrations were quite different during all chamber experiments. The SMPS mass concentrations were lower by approximately a factor of 5 for a density of 1 g cm^{-3} compared to the AMS total concentrations. Thus, an additional chamber experiment was conducted, where AMS and SMPS concentrations were compared to gravimetric measurements of the concentrations of COA samples collected on Teflon filters. For the same period the AMS mass concentration ($\text{CE} = 1$) was $600 \mu\text{g m}^{-3}$, the SMPS (assuming density 1 g cm^{-3}) was $100 \mu\text{g m}^{-3}$, and the filter-based concentration was $500 \mu\text{g m}^{-3}$. This intercom-

parison shows that the SMPS mass concentrations assuming spherical particles are problematic probably because the fresh particles emitted from charbroiling are non-spherical. Katrib et al. (2005) reported that during the ozonolysis of stearic acid needle-shaped particles were identified by transmission electron microscopy. SEM pictures of fresh COA particles in our experiments also suggested that the particles were not spherical. However, particles evaporate in the SEM so the proof is not conclusive. Given that CE values less than unity would further increase the disagreement between the AMS and the SMPS estimates and that the density of COA should be less than 2 g cm^{-3} , we estimate that the non-spherical shape of the particles introduces an error of the order of 2–4 in the volume concentration estimated by the SMPS measurements.

3.2 COA emission rates

Gravimetric analysis of the samples collected from above the charbroiler yielded an aerosol emission factor of 4 g kg^{-1} of meat cooked. Hildemann et al. (1991) studied the emissions from hamburger cooking of regular and lean meet either by frying or charbroiling and reported emissions between 1 and 40 g kg^{-1} . McDonald et al. (2003) determined the emission ratios of meat cooking (hamburger, steak, and chicken) due to charbroiling or grilling and reported emission rates in the range $4\text{--}12 \text{ g kg}^{-1}$ (McDonald et al., 2003). These rates vary by more than 1 order of magnitude not only because different types of meat were cooked but also due to the different cooking procedures (charbroiling, grilling, frying, etc.), and cooking specifics (well-done, medium, slowly cooked, medium cooking time, etc.). Generally charbroiling emits more particles than frying and also the emissions increase with increasing fat content of the meat cooked. There is also additional variability related to where the meat is placed with respect to the very hot surfaces (e.g., charcoal). In the present study we tried to duplicate the cooking conditions and practices used in Greece.

3.3 Emissions of volatile organic compounds

Several VOCs were emitted during cooking though their concentrations compared to the PM were low. In most cases less than 1 ppb of a specific VOC was emitted per $100 \mu\text{g m}^{-3}$ of PM. The aromatic species (benzene, toluene, xylenes) were emitted in similar amounts (0.1 g kg^{-1}). Table 3 presents the emission factors for some of the measured VOCs based on a COA emission rate of 4 g kg^{-1} of meat. To the best of our knowledge there is little information about VOC emissions from cooking. For example, Schauer et al. (1999) reported the emission factors from meat charbroiling over a natural gas-fired grill. So our major objective was to add to this limited literature. Based on the emissions measured the SOA formation potential of cooking would be limited compared to the primary emissions. This is consistent with the limited

Table 3. Emission factors (g kg^{-1} of meat cooked) for several VOCs.

VOC	PTR-MS <i>m/z</i>	Emission rate (g kg^{-1})
Acetonitrile	42	0.01 ± 0.00
Acetone	59	0.03 ± 0.01
Isoprene	69	0.05 ± 0.01
MVK and MACR	71	0.03 ± 0.01
MEK	73	0.01 ± 0.01
Benzene	79	0.09 ± 0.02
Toluene	93	0.09 ± 0.03
Xylenes	107	0.10 ± 0.04
Monoterpenes	137	0.04 ± 0.02

additional SOA that we have observed experimentally as discussed in the next section. There was no detectable decrease of the concentrations of the VOCs measured by the PTR-MS during the characterization periods.

3.4 Chemical aging of COA

Significant changes to the COA spectrum were observed during its oxidation. The initial and final O : C and H : C ratios for all the experiments are reported in Table 1. For Experiment 1, in which the emissions were illuminated for 4 h the O : C increased from 0.11 to 0.27. For Experiment 2, where the UV lights were turned on for 8 h, the O : C reached 0.30. For Experiment 3, in which dark ozonolysis took place, the O : C ratio reached 0.21 2 h after the addition of 40 ppb of ozone. For experiment 4 the O : C ratio reached 0.27 after 7.5 h of exposure to UV. No change was seen for the O : C and H : C ratios for Experiment 5 in which the COA was left in the chamber without addition of oxidants or exposure to UV.

For the experiments in which UV illumination was used the O : C ratio increased from 0.1 to 0.2 in less than 2 h. For Experiment 3, in which 40 ppb of O_3 were added, the O : C ratio increased from 0.12 to 0.18 in less than 1 h. Figure 3a shows the temporal evolution of the O : C ratios during the five smog chamber experiments. In Experiment 3 (dark ozonolysis) an increase prior to the addition of ozone was seen due to small amounts of ozone (approximately 9 ppb) initially present in the chamber. Figure 3b presents the corresponding H : C ratio evolution during the five experiments. A reduction in H : C by 10 % or so was observed in all experiments.

The θ angles between the fresh and aged COA AMS spectra are summarized in Table 1. Differences in the AMS spectra between the fresh and aged COA were present throughout the *m/z* range. The fractional contribution of *m/z* 44, f_{44} , increased during the UV aging and the dark ozonolysis. Figure 1b shows the aged COA HR spectrum for Experiment 2 (after 8 h of UV illumination). After aging with UV for 4 h

Figure 3. (a) O:C ratios and (b) H:C ratios for the COA smog chamber experiments. Time zero corresponds to the beginning of the aging process.

Figure 4. Evolution of the θ angle with the initial AMS mass spectrum during aging.

the θ angle was 22° in experiment 1. The addition of ozone resulted in a 15° shift in 4 h. The relatively fast change in the AMS spectra is noteworthy (Fig. 4). After 1 h of UV illumination a θ angle of 12° was observed. For the dark ozonolysis

experiment a 15° change was observed 2 h after the ozone addition. These results indicate that the COA emitted from meat charbroiling can change rapidly after it is emitted either during the day (when it is sunny) or during the night when moderate levels of ozone are available.

Figure 5a shows the fraction of m/z 44 (f_{44}) and m/z 43 (f_{43}) as they evolve over time during Experiment 2 (8 h of UV). Most of the COA factors reported in the literature fall in the lower left part of the Ng triangle (Ng et al., 2011). After the oxidation process the system position tends to move up as f_{44} increases. A similar trend was observed for the f_{55} to f_{57} plot (Fig. 5b) where both fractions decrease due to chemical aging. A similar behavior was observed during ozonolysis (Fig. 5c and d).

The driving forces for these chemical aging processes were reactions with O₃ and OH radicals. Significant O₃ production was observed in the UV illumination experiments with at least 40 ppb of O₃ produced after a few hours of illumination. During the first hour, 15 ppb was formed and after 2 h the ozone concentration reached 25 ppb. At the same time the OH radical concentration increased up to 5×10^6 molecules cm⁻³. Figure 6a depicts the O₃ and OH concentrations for Experiment 2 in which UV illumination was used. Similar results were obtained for the rest of the UV illumination experiments. Figure 6b shows the O₃ evolution during the dark ozonolysis experiment. After the initial addition of 40 ppb of ozone, approximately 5 ppb was consumed during the first 3 h.

Net OA production due to chemical aging was limited. In the five experiments OA mass enhancements (after corrections for particle losses) were less than 10% of the mass prior to the perturbation. This small change in mass strongly suggests that a lot of the observed chemical changes were probably due to heterogeneous reactions. Such reactions can explain the significant changes in composition (e.g., O:C) and the small additional OA formation in these experiments. Kroll et al. (2015) observed similar changes in aerosol chemical composition during exposure to OH but at exposures that were more than 1 order of magnitude higher than those in our experiments. However, studies of the ozonolysis of COA components like oleic acid (e.g., Morris et al., 2002) suggest that the corresponding reactions have timescales of as little as minutes. These literature results suggest that ozonolysis was probably the dominating chemical aging pathway in our experiments.

While VOC concentrations remained stable when no UV light or oxidants were used, the concentrations of formaldehyde, acetaldehyde, formic acid, acetone, acetic acid, and methyl ethyl ketone all increased during the chemical aging. Approximately 15 ppb / $100 \mu\text{g m}^{-3}$ of COA of acetaldehyde and 8 ppb / $100 \mu\text{g m}^{-3}$ of COA of formaldehyde were produced during the exposure to UV and O₃. The increase of the concentration of these relatively small compounds suggests that fragmentation of the mostly larger organic molecules emitted during meat charbroiling is taking place. It is not

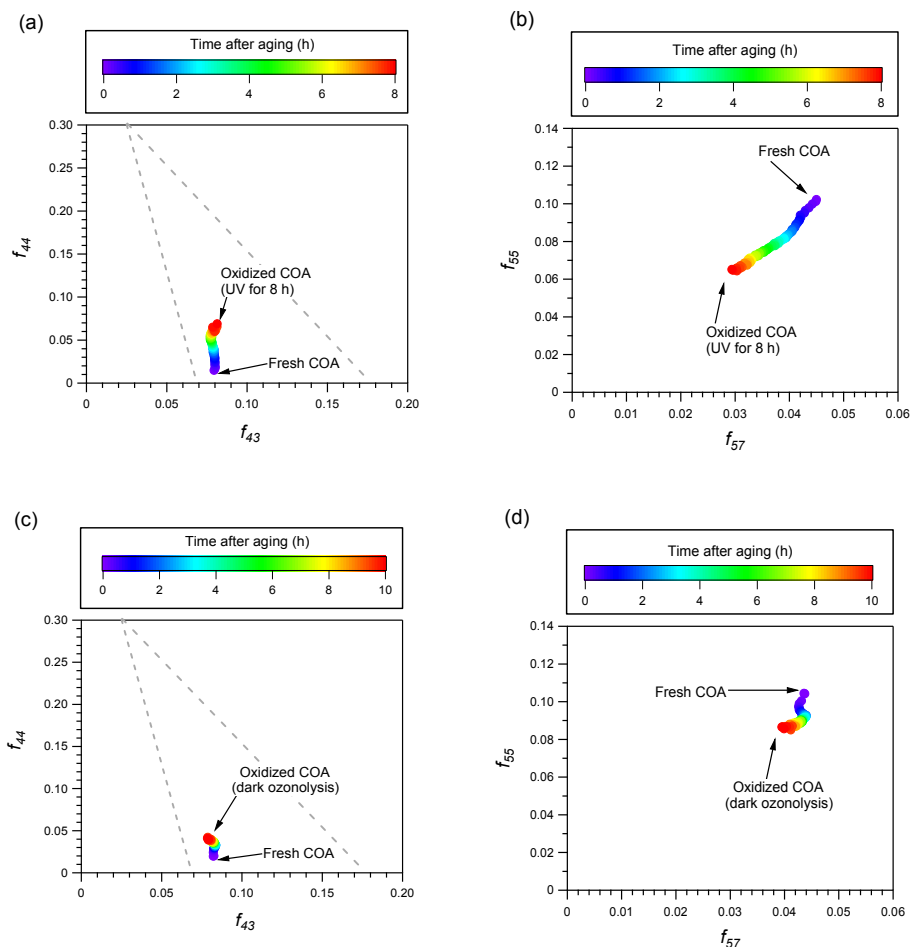

Figure 5. Scatter plot for the fractions of signal for Experiment 2 (UV for 8 h) and Experiment 3. (a) f_{44} to f_{43} for Experiment 2, (b) f_{55} to f_{57} for Experiment 2, (c) f_{44} to f_{43} for Experiment 3, and (d) f_{55} to f_{57} for Experiment 3.

clear whether these molecules are products of the organics in the particulate phase (that is products of the heterogeneous reactions) or whether they were produced in the gas phase.

The water solubility of the COA also increased during its chemical aging. The WSOC / OC ratio for the fresh emissions was measured in each experiment and was always low with values in the 0.05–0.13 range. The WSOC / OC ratio after chemical aging was measured in three experiments, two after UV illumination (experiments 1 and 2) and one after dark ozonolysis (Experiment 3). In all these three experiments the WSOC / OC ratio increased: to 0.7 for Experiment 1, 0.85 for Experiment 2, and 0.55 for Experiment 3. This shows that the WSOC / OC ratio of the aged COA is significantly higher than that of the fresh emissions and that the COA became a lot more hygroscopic as it aged.

HR-PMF analysis was performed for each chamber experiment separately. More information is provided in the Supplement (Sect. S1, Figs. S1–S18). For experiments 1–4 two factors were identified: a fresh and an aged factor. Figure 7 shows the mass spectra of the two factors for Experiment 1.

The mass spectra of the fresh COA factors had an O : C ratio of 0.09–0.11 and they were very similar each other ($R^2 > 0.992$, $\theta < 7^\circ$). They were also close to the average fresh mass spectrum from all five experiments ($R^2 > 0.96$, $\theta < 10^\circ$). The aged factors had an O : C ratio in the range of 0.20–0.26 depending on the degree of oxidation. The AMS spectra of the aged factors after exposure to UV (experiments 1, 2, and 4) were similar to each other (θ ranging from 2 to 6°). The corresponding angles between the dark ozonolysis experiment (Experiment 3) and the UV exposure ones were higher ranging from 8 to 14° as the dark ozonolysis factor was less oxidized. Figure 8 illustrates the time series of the two factors for Experiment 3 (O₃) and Experiment 4 (UV).

4 Ambient measurements

Ambient aerosol was sampled outside the ICE-HT institute (8 km NE from the city center of Patras) during February 2012 for a period of 2 days. This period included Fat Thurs-

component particles was 0.76 ± 0.07 . Applying HR-PMF analysis (using PET) on the AMS spectra for these 2 days of measurements, four sources were identified. PMF solutions up to five factors were examined and evaluated, while the tested f_{peak} range was between -2 and 2 . More informa-

Figure 10. Mass spectra of the four PMF factors found for the measurement period including Fat Thursday (16 February 2012).

tion for the selection of the factors is provided in Sect. S2 and Figs. S19–S23. One factor was related to OOA, while the other three factors were attributed to primary emissions: transportation (HOA), burning of olive tree branches (otBBOA), and meat cooking (COA). Given the small dataset, the stability of the solution was further investigated using ME-2 analysis (SoFi) and applying a constrained solution for the HOA using the HOA mass spectrum of Kostenidou et al. (2013) with $a = 0.1$ (Sect. S3, Figs. S24–S28). There was no significant change in the factors in the two solutions. More details are given in Sect. S3 and Figs. S23–S26. The cooking mass spectrum and time series did not change significantly with an $R^2 > 0.99$ between PMF and ME-2 solutions.

Figure 9 shows the mass concentrations of the four factors. During midday on Fat Thursday, the organic mass concentration was $23.2 \mu\text{g m}^{-3}$, representing 81 % of the PM_{10} . For the same period the cooking-related factor represented 85 % of the organic aerosol ($17.5 \mu\text{g m}^{-3}$), while for the day before and the day after the COA factor represented only 5 % of the total OA. From various studies that were conducted in Greek cities, COA appears to be 15–20 % of the OA (Kostenidou et al., 2015; Florou et al., 2017). The mass spectrum of the COA along with the rest of the factors obtained by the PMF analysis is shown in Fig. 10. The m/z values contributing significantly to the COA factor were 39, 41, 43, 44, 55, 57, 67, 69, 71, etc., which are characteristic of cooking OA found in previous studies (Ge et al., 2012; Crippa et al., 2013a, b).

Figure 11 summarizes the angle θ between the mass spectra of the fresh and aged meat charbroiling OA and the PMF COA factors from ambient measurements from other studies. Depending on atmospheric conditions (oxidant levels) the COA AMS spectrum can be different. This can be seen by the comparison of fresh and aged COA in these experiments against the summer and winter COA factors in Greece. Other factors that appear to drive variability can include the PMF

analysis itself (e.g., mixing with other sources), the type of food cooked, etc. The fresh laboratory COA spectrum has many similarities with the COA factors obtained in Athens and Patras during the winter (θ angles of 13° in both cases) especially considering that these are independent PMF results from different campaigns. In contrast, the aged COA spectrum is similar to the cooking-related factors (HOA-2) identified during the summer in both cities (θ angles of 9° for both). The spectrum of the cooking OA of Fat Thursday in Patras (a sunny period with moderate temperatures) was quite similar with the aged meat charbroiling aerosol. This demonstrates that COA ages relatively fast under ambient conditions when the necessary oxidants are available (i.e., sunny summer days) and as a result PMF analysis can distinguish only one factor (the aged COA). Even though this conversion is rapid the COA does not reach high-oxidation states comparable to those of OOA. In addition, our results suggest that before performing PMF analysis using default COA spectra as external factors, one should account for their potential chemical aging.

The aged COA spectrum from our chamber experiments is similar to the COA factor reported by Sun et al. (2011) for the city of New York during summer (Fig. 11). This is also true for the COA-related factor (CIOA) reported by Hayes et al. (2013) for the 2010 CalNex campaign in Pasadena, CA. However, the COA factors reported for Fresno (Ge et al., 2012) and Paris (Crippa et al., 2013b) were in better agreement with the fresh COA reported in this work.

5 Conclusions

Particulate emissions from meat charbroiling consist mainly of organics (> 99 %) while BC is only 0.3 %. These fresh OA emissions react rapidly with ozone and OH radicals with significant changes in their AMS spectra. After 2 h of UV illumination (average OH concentration of $3 \times 10^6 \text{ cm}^{-3}$) the O:C ratio doubles and the aged spectrum differs approximately 15° from the fresh one. Fresh COA is hydrophobic (WSOC-to-OC ratio of 0.05–0.15) while the aged COA is more hydrophilic (WSOC-to-OC ratio of 0.7–0.85).

The AMS spectrum of the fresh laboratory COA was similar (θ less than 10°) to the ambient PMF COA winter factors in two major Greek cities, while it was quite different (θ 20– 35°) from the ambient summertime COA factors. The opposite behavior was observed for the aged COA, which was similar to the ambient summertime PMF COA factors (θ 10– 12°). These results suggest that the degree of chemical aging of the COA has to be taken into account for source identification in the PMF analysis of ambient AMS datasets.

The laboratory experiments were conducted at concentrations higher than atmospheric and this could be a potential limitation of the aging experiments. However, the concentrations in Experiment 1 when aging began were only a factor of 4 higher than the ambient COA levels shown in Fig. 9, so they

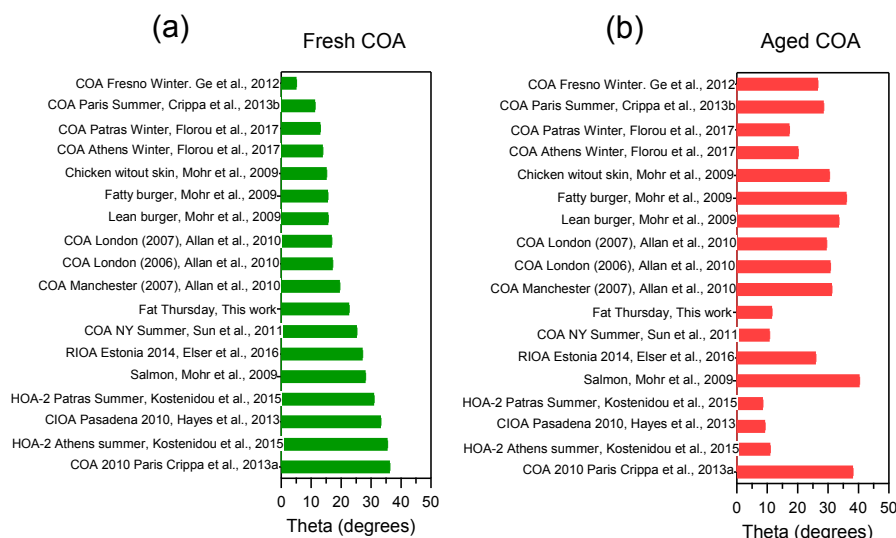

Figure 11. Angles θ between COA factors and the (a) fresh meat charbroiling emissions (average fresh spectrum) and (b) aged (average of the UV exposure experiments) meat charbroiling emissions.

are by no means unreasonable. The fact that we did not observe significant differences in behavior with initial concentration (the investigated variation was also a factor of 4) and the relatively good agreement of the aged laboratory COA AMS spectra with the ambient spectra suggests that the effect of the COA levels was probably not a serious limitation. The volatility of the cooking organic aerosol in these experiments as well as during the field campaign is discussed in a forthcoming publication.

Data availability. The related data are available on request from Spyros Pandis (spyros@chemeng.upatras.gr).
