Abstract. Recently, liquid–liquid phase separation (LLPS) of secondary organic aerosol (SOA) particles free of inorganic salts has been intensively studied due to the importance of cloud condensation nuclei (CCN) properties. In this study, we investigated LLPS in four different types of SOA particles generated from α-pinene ozonolysis and α-pinene photooxidation in the absence and presence of ammonia (NH₃). LLPS was observed in SOA particles produced from α-pinene ozonolysis at ~95.8 % relative humidity (RH) and α-pinene ozonolysis with NH₃ at ~95.4 % RH. However, LLPS was not observed in SOA particles produced from α-pine photooxidation and α-pinene photooxidation with NH₃. Based on datasets of the average oxygen to carbon elemental ratio (O : C) for different types of SOA particles from this study and from previous studies, there appears to be a relationship between the occurrence of LLPS and the O : C of the SOA particles. When LLPS was observed, the two liquid phases were present up to ~100 % RH. This result can help more accurately predict the CCN properties of organic aerosol particles.

1 Introduction

Secondary organic aerosol (SOA) particles in the atmosphere can be formed by the oxidation of volatile organic compounds (VOCs) emitted from biogenic and anthropogenic sources (Hallquist et al., 2009). These SOA particles may comprise a large fraction of ultrafine aerosol particles depending on the location (Zhang et al., 2007; Jimenez et al., 2009). They can affect the energy balance of the Earth by scattering and absorbing solar radiation and also by acting as nuclei for cloud formation (Kanakidou et al., 2005; Hallquist et al., 2009; IPCC, 2013; Knopf et al., 2018). In addition, these particles can affect air quality and human health (Kanakidou et al., 2005; Jang et al., 2006; Forster et al., 2007; Baltensperger et al., 2008; Murray et al., 2010; Wang et al., 2012; Pöschl and Shiraiwa, 2015; Shiraiwa et al., 2017).

Many previous studies have shown that SOA particles can be formed more efficiently in the presence of gaseous species such as ammonia (NH₃) (Zhang et al., 2004; Na et al., 2006, 2007; Laskin et al., 2014; T. Y. Liu et al., 2015; Y. Liu et al., 2015; Babar et al., 2017). NH₃ is one of the abundant and reactive gaseous species in the atmosphere (Reis et al., 2009; Heald et al., 2012; Reche et al., 2015; Zheng et al., 2015; Sharma et al., 2016; Warner et al., 2016). The chemical composition of SOA particles can be influenced by reaction with NH₃ (Laskin et al., 2015; Y. Liu et al., 2015b), but the chemical composition from the reaction is still poorly understood.
Aerosol particles containing SOAs can undergo phase transitions in the atmosphere as relative humidity (RH) changes. Thus far, many researchers have focused on phase transitions, especially liquid–liquid phase separation (LLPS) in particles containing SOAs and inorganic salts during changes in RH (Pankow, 2003; Marcolli and Krieger, 2006; Ciobanu et al., 2009; Bertram et al., 2011; Krieger et al., 2012; Song et al., 2012a, b; Zuend and Seinfeld., 2012; Ault et al., 2013; Veghte et al., 2013; O’Brien et al., 2015). They established that LLPS always occurs in SOA particles mixed with inorganic salts when the oxygen to carbon elemental ratio (O : C) of the organic materials is lower than 0.56, whereas LLPS never occurs when the O : C of the organic materials is higher than 0.80. LLPS commonly occurs in the intermediate O : C range (Bertram et al., 2011; Krieger et al., 2012; Song et al., 2012a, 2013; You et al., 2013, 2014). LLPS in a mixture of SOA particles and inorganic salts is known to affect the optical properties (Fard et al., 2018), gas–particle partitioning (Zuend et al., 2010; Zuend and Seinfeld, 2012; Shiraia et al., 2013), reactivity (Kuwata and Martin, 2012), hygroscopic properties (Hodas et al., 2016) and cloud condensation nuclei (CCN) properties of these particles (Hodas et al., 2016; Ovdnevaita et al., 2017; Rastak et al., 2017; Altan et al., 2018).

More recently, researchers have focused on LLPS in SOA particles in the absence of inorganic salts (Petters et al., 2006; Renbaum-Wolf et al., 2016; Rastak et al., 2017; Song et al., 2017, 2018) as it is important to explore the CCN properties of the particles (Petters et al., 2006; Hodas et al., 2016; Renbaum-Wolf et al., 2016; Ovdnevaita et al., 2017; Rastak et al., 2017; Liu et al., 2018). Renbaum-Wolf et al. (2016) and Song et al. (2017) observed LLPS at a high RH of 95%-100% in SOA particles produced from the ozonolysis of α-pinene, β-caryophyllene and limonene. However, Rastak et al. (2017) and Song et al. (2017) did not observe LLPS in SOA particles produced from the photooxidation of isoprene and toluene. The occurrence of LLPS in SOA particles free of inorganic salts was related to the average O : C of the organic materials. When the average O : C of the SOA particle was less than ~0.44, LLPS was observed in the SOA particles free of inorganic salts (Renbaum-Wolf et al., 2016; Rastak et al., 2017; Song et al., 2017). Song et al. (2018) studied organic particles consisting of one and two commercially available organic species free of inorganic salts and found that the average O : C of the organic material can be an important parameter to predict LLPS. LLPS was observed in particles containing one organic species at an O : C of ≤ 0.44 and in particles containing two organic species at an O : C of ≤ 0.58. As few systems have been studied thus far, more studies are needed to confirm the effect of O : C on the LLPS in organic particles.

Herein, we investigated LLPS in SOA particles produced from the ozonolysis and photooxidation of α-pinene. Moreover, we studied the effects of NH₃ on SOA particles produced from the ozonolysis and photooxidation of α-pinene on the occurrence of LLPS.

2 Experimental

2.1 Production of SOA particles

Four different types of SOA particles were generated in the flow tube reactor of Kyungpook National University (KNU), South Korea: those produced via α-pinene ozonolysis and α-pinene photooxidation in the absence of NH₃ (Table 1), and those produced via α-pinene ozonolysis and α-pinene photooxidation in the presence of NH₃ (Table 2). The method of SOA particle generation was previously described by Babar et al. (2017). The flow tube reactor was run at a flow rate of 4.0 L min⁻¹, with a residence time of 3.63 min at ~10% RH.

α-pinene at a concentration of 1000 ppb was injected into the flow tube reactor to produce SOA particles via ozonolysis without NH₃. O₃ was produced by passing high purity O₂ through a UV lamp (λ = 185 nm) and was injected into the flow tube reactor at a concentration of 10 000 ppb. Table 1 presents the experimental conditions for the ozonolysis.

To produce SOA particles via photooxidation in the absence of NH₃, 1000 ppb of α-pinene was injected in the flow tube reactor (Table 1). The OH radical was produced by photodissociation of O₃ by irradiating O₃ with UV (λ = 254 nm) in the presence of water vapor. The following photochemical reactions take place:

\[ \text{O}_3 + \text{hv} \rightarrow \text{O}_2 + \text{O} \]  \quad (R1)

\[ \text{O} + \text{H}_2\text{O} \rightarrow \text{2OH} \]  \quad (R2)

In the flow tube reactor, OH concentrations were determined from the photochemical decay of toluene, as toluene is well known for its OH reaction rate. The OH reaction rate constant \((k_{\text{OH}})\) of toluene is 5.48 × 10⁻¹² molecules cm⁻³ s⁻¹ with an insignificant reaction rate with O₃ (Atkinson and Aschmann, 1989). The OH concentrations were calculated by varying O₃ and RH from 2000 to 8000 ppb and 10% to 60%, respectively. The OH concentrations were calculated by the first-order decay of toluene by reaction with OH radicals (Babar et al., 2017). Assuming an atmospheric OH concentration of 1.5 × 10⁹ molecules cm⁻³, OH exposures were 8.2 × 10¹⁰ and 2.3 × 10¹¹ molecules cm⁻³ s⁻¹, corresponding to an atmospheric aging time of 0.5 and 2.5 days, respectively, and the concentrations of O₃ in the reactor were 2000 and 6000 ppb at 10% RH, respectively.

The same method was used for the SOA particle generation via ozonolysis and photooxidation in the presence of NH₃, the exception being that NH₃ was injected into the flow tube reactor during particle generation. The concentration of NH₃ injected was 2000 ppb for the ozonolysis and photooxidation (Table 2). The 4 L min⁻¹ mainstream flow of SOA particles at the outlet of the flow tube reactor was diluted by a humidified air.
Table 1. Experimental conditions for production and collection of SOA particles from α-pinene ozonolysis (termed “α-pinene O₃”) and photooxidation (termed “α-pinene OH”). The separation relative humidity (SRH) upon moistening and the merging relative humidity (MRH) upon drying are listed. The SRH is the RH at which liquid–liquid phase separation occurred. The MRH is the RH at which two phases merged into one phase. The uncertainties indicate the 2σ from several humidity cycles for one sample and from the uncertainty of the calibration. SRH and MRH values of zero indicate that phase separation was not observed. “conc.” refers to concentration.

A diffusion dryer loaded with silica gel was used upstream of the scanning mobility particle sizer (SMPS) with silica gel was used upstream of the scanning mobility particle sizer (SMPS) for the measurement of dry SOA mass concentrations. After dilution, the mass concentrations of the SOA particles were measured to range between ~480 and ~880 µg m⁻³ using the SMPS for different experimental conditions as presented in Tables 1 and 2. The sample and sheath flow rates of the SMPS were 0.3 and 3.0 L min⁻¹, respectively. The SOA particles consisting of up to ~5 µm were collected at the outlet of the reactor on a siliconized substrate (siliconized glass slides of 18 mm, Hampton Research, USA). Figure S1 in the Supplement is an example image of collected SOA particles derived from α-pinene ozonolysis (α-pinene O₃ no. 1 in Table 1) on a hydrophobic substrate at the outlet of the flow tube reactor.

For each experiment, the siliconized glass slide was initially cleaned three times with water and methanol. It was then dried by purging N₂ gas. Finally, it was fixed in the Stage D collector plate of a Sioutas cascade impactor (SKC cat no. 225–370, USA), operated at 9 L min⁻¹.

2.2 Observation of liquid–liquid phase separation in SOA particles

The observation of LLPS in a particle requires particle diameters of 20–80 µm. In order to obtain the appropriate particle sizes for the LLPS experiments, SOA particles sized up to 5 µm collected on the siliconized substrate from the flow tube reactor were placed into a RH-controlled flow-cell coupled to an optical microscope (Olympus BX43, 40 × objective) (Parsons et al., 2004; Pant et al., 2006; Bertram et al., 2011; Song et al., 2012b, 2018) at ~100 % RH; the particles then grew and coagulated for ~60 min. This process resulted in a particle size of 20–80 µm (Renbaum-Wolff et al., 2016). Once the particle size was appropriate for the LLPS experiments, humidity cycles were performed.

During a humidity cycle, the RH was reduced from ~100 % to ~5–10 % lower than the RH at which the two liquid phases merged into one phase, followed by an increase to ~100 % RH at a rate of 0.1 %–0.5 % RH min⁻¹. If LLPS was not observed, the RH was reduced from ~100 % to ~0 %, and then it was increased to ~100 % at a rate of
0.5–1.0 % RH min\(^{-1}\). We did not observe a dependence of LLPS on the humidity ramp rate. The optical images of the SOA particles during the experiment were recorded every 5 s using a complementary metal oxide semiconductor detector (DigiRetina 16, Tucsen, China). All of the experiments were performed at a temperature of 289 ± 0.2 K.

The RH was controlled by the ratio of \(\text{N}_2/\text{H}_2\text{O}\) gas at a total flow rate of 500 sccm. The RH inside the flow-cell was determined using a temperature and humidity sensor (Sensirion SHT71, Switzerland) which was calibrated by observing the deliquescence RH for the following pure inorganic salts at 293 K: potassium carbonate (44 % RH), sodium chloride (76 % RH), ammonium sulfate (80.5 % RH) and potassium nitrate particle (93.5 % RH) (Winston and Bates, 1960). The uncertainty of the RH after calibration was ±2.0 %.

3 Results and discussion

3.1 SOA particles produced from \(\alpha\)-pinene ozonolysis and \(\alpha\)-pinene photooxidation

SOA particles generated by \(\alpha\)-pinene ozonolysis with a mass concentration of \(\sim 500–1000 \mu\text{g m}^{-3}\) underwent humidity cycles at 289 ± 0.2 K. Figure 1 shows examples of optical images of a SOA particle (\(\alpha\)-pinene O\(_3\) no. 1 in Table 1) produced from \(\alpha\)-pinene ozonolysis with increasing RH. Only one phase was observed from 0 to \(\sim 96\%\) RH (Fig. 1). At 96.6 % RH, LLPS occurred via a spinodal decomposition mechanism, which distributes many small inclusions (schlieren) throughout a particle (Ciobanu et al., 2009; Song et al., 2012b). After phase separation, at \(\sim 97.0\%\) RH, small droplets grew and coagulated to form inner and outer phases in the particle. As the RH increased further, the SOA particle displayed a core–shell morphology consisting of inner and outer phases. The two liquid phases coexisted up to \(\sim 100\%\) RH, as shown in Fig. 1. When the RH decreased from \(\sim 100\%\), the inner phase became smaller and merged into one phase at \(\sim 95.0\%\) RH. We assume that the inner phase is a water-rich phase and the outer phase is an organic-rich phase as the size of the inner phase depends on changes in RH (Renbaum-Wolff et al., 2016; Song et al., 2017, 2018).

Table 1 summarizes the separation relative humidity (SRH) upon moistening and the merging relative humidity (MRH) upon drying. In all cases, the SOA mass concentration was \(\sim 500–1000 \mu\text{g m}^{-3}\). LLPS was observed at 95.8±2.3 % RH for all SOA particles derived from \(\alpha\)-pinene ozonolysis, and the two phases merged into one phase at 92.9±4.6 % RH. The uncertainties of the SRH and the MRH indicate the 2\(\sigma\) from several humidity cycles for one sample and from the uncertainty of the calibration.

Renbaum-Wolff et al. (2016) observed LLPS in SOA particles derived from \(\alpha\)-pinene ozonolysis at \(\sim 95\%\) RH, which is consistent with our result. They also showed that LLPS in the particles did not depend on the SOA particle mass concentrations between 75 and 11 000 \(\mu\text{g m}^{-3}\). As the SOA particle mass concentration does not affect LLPS, in this study, we only focused on SOA particle mass concentrations between \(\sim 500\) and 1000 \(\mu\text{g m}^{-3}\) for different types of SOA particles.

We also performed humidity cycles for SOA particles with mass concentrations between \(\sim 500\) and 1000 \(\mu\text{g m}^{-3}\) derived from \(\alpha\)-pinene photooxidation. Table 1 summarizes the results of the humidity cycles. None of the SOA particles from \(\alpha\)-pinene photooxidation underwent LLPS during the RH cycles. Figure 2 shows examples of optical images of a SOA particle (\(\alpha\)-pinene OH no. 2 in Table 1) for increasing RH. From 0 % RH to 100 % RH, there was no evidence of the occurrence of LLPS in the particles.

3.2 SOA particles produced from \(\alpha\)-pinene ozonolysis with \(\text{NH}_3\) and \(\alpha\)-pinene photooxidation with \(\text{NH}_3\)

Ammonia (\(\text{NH}_3\)) is an abundant and reactive gaseous species in the atmosphere (Reis et al., 2009; Heald et al., 2012; Reche et al., 2015; Zheng et al., 2015; Sharma et al., 2016; Warner et al., 2016). Previous studies have shown that SOA particles can be formed more effectively in the presence of \(\text{NH}_3\) (Zhang et al., 2004; Na et al., 2006, 2007; T. Y. Liu et al., 2015; Y. Liu et al., 2015; Babar et al., 2017). To investigate the effect of \(\text{NH}_3\) on LLPS in SOA particles, we studied LLPS in SOA particles using \(\alpha\)-pinene ozonolysis and photooxidation in the presence of \(\text{NH}_3\). Table 2 presents the experimental conditions for the particle generation. We used the experimental conditions of SOA particle generation via ozonolysis and photooxidation (Table 1) in this case too, but we injected 2000 ppb of \(\text{NH}_3\) into the flow tube reactor during particle generation (Table 2).

We performed humidity cycles for the SOA particles produced from \(\alpha\)-pinene ozonolysis in the presence of \(\text{NH}_3\) for mass concentrations between \(\sim 500\) and 1000 \(\mu\text{g m}^{-3}\). Figure 3 shows examples of the optical images of SOA particles produced by \(\alpha\)-pinene ozonolysis in the presence of \(\text{NH}_3\) as a function of increasing RH (\(\alpha\)-pinene O\(_3\)/\(\text{NH}_3\) no. 1 in Table 2). Upon moistening, only one phase was present (Fig. 3). As RH increased, the one phase of the SOA particle was separated into two phases at 95.3 % RH; the underlying mechanism for this separation was spinodal decomposition. At 95.6 % RH, small inclusions in the particle coagulated and grew; then, as RH increased further, a core–shell morphology, with a shell consisting of an organic-rich phase and the core consisting of a water-rich phase on a substrate, was observed. The two liquid phases coexisted up to \(\sim 100\%\) RH. When the RH decreased from \(\sim 100\%\), the inner phase of the particle became smaller, and, eventually, the inner phase merged into one phase at 94.4 % RH.

Table 2 summarizes the results of average SRH and MRH during the humidity cycles for the SOA particles produced by \(\alpha\)-pinene ozonolysis in the presence of \(\text{NH}_3\). LLPS occurred
Figure 1. Optical images of a SOA particle produced from α-pinene ozonolysis (α-pinene O₃ no. 1 in Table 1) with increasing RH. The purpose of the illustrations is to clarify the images. Green is the SOA-rich phase, and blue is the water-rich phase. The scale bar is 20 µm.

Figure 2. Optical images of a SOA particle produced from α-pinene photooxidation (α-pinene OH no. 2 in Table 1) with increasing RH. The purpose of the illustrations is to clarify the images. Green is the SOA-rich phase, and blue is the water-rich phase. The scale bar is 20 µm.

at 95.4±2.9 % RH, and the two phases merged into one phase at 94.4±2.7 % RH for all of the particles (Table 2).

For SOA particles derived from α-pinene photooxidation in the presence of NH₃, no LLPS was observed during changes in RH. Table 2 lists the results of SRH and MRH for two different SOA particles derived from α-pinene photooxidation in the presence of NH₃. Figure 4 shows the examples of the optical images of SOA particles produced by α-pinene with NH₃ photooxidation for increasing RH (α-pinene OH/NH₃ no. 2 in Table 2). Only one phase was observed from 0 % RH to 100 % RH.

3.3 Phases of the four different types of SOA particles

Figure 5 shows the RH at which two liquid phases were observed during RH scanning for the four different types of SOA particles. Circles represent the MRH upon drying, and triangles represent the SRH upon moistening. In the figure, the values of the SRH and MRH of SOA particles derived from α-pinene ozonolysis by Renbaum-Wolff et al. (2016) are also included (in red). If the RH equals 0 %, no LLPS was observed.

Among the four different types of SOA particles, two types of particles underwent LLPS but the remaining particles did not (Fig. 5). For the SOA particles derived from α-pinene ozonolysis, two liquid phases existed at ∼ 95.8 ± 2.3 % RH up to ∼ 100±2.0 % RH with increasing RH. For values lower than ∼ 92.9±4.6 % RH with decreasing RH, only one phase was observed. For the SOA particles derived from α-pinene ozonolysis in the presence of NH₃, the RH ranges for the two liquid phases were ∼ 95.4±2.9 % and ∼ 100±2.0 % with increasing RH. SRH values of both SOA particles were very similar within the uncertainties of the measurements. Furthermore, Fig. 5 showed that the values of SRH upon moistening and MRH upon drying for the two types of particles were close within the uncertainties of the measurements, suggesting that the kinetic barrier to LLPS in the particles is low.

Compared with the SOA particles derived from α-pinene ozonolysis and from α-pinene ozonolysis with NH₃, LLPS was not observed in SOA particles derived from α-pinene photooxidation without/with NH₃ (Fig. 5). In these cases, only one phase was present between 0 % RH and 100 % RH.

3.4 Relation between O : C ratio and LLPS

Recent studies have shown that the occurrence of LLPS in SOA particles free of inorganic salts is related to the average O : C of the organic materials (Renbaum-Wolff et al., 2016;
9326 S. Ham et al.: Liquid–liquid phase separation in secondary organic aerosol particles

Figure 3. Optical images of a SOA particle produced from α-pinene ozonolysis with NH₃ (α-pinene O₃/NH₃ no. 1 in Table 2) with increasing RH. The purpose of the illustrations is to clarify the images. Green is the SOA-rich phase, and blue is the water-rich phase. The scale bar is 20 µm.

Figure 4. Optical images of a SOA particle produced from α-pinene photooxidation with NH₃ (α-pinene OH/NH₃ no. 2 in Table 1) with increasing RH. The purpose of the illustrations is to clarify the images. Green is the SOA-rich phase, and blue is the water-rich phase. The scale bar is 20 µm.

Rastak et al., 2017; Song et al., 2017). These studies have shown that LLPS can occur in SOA particles derived from α-pinene, limonene and β-caryophyllene for RH values between ~95 % and ~100 % when the average O : C ranged between 0.34 and 0.44. LLPS was not observed in SOA particles derived from isoprene and toluene when the average O : C was between 0.52 and 1.30. Figure 6 and Table S1 in the Supplement show LLPS as a function of the average O : C of SOA particles from previous studies (Lambe et al., 2015; Li et al., 2015; Renbaum-Wolff et al., 2016; Song et al., 2017). Also presented in Table S2 are the O : C values and experimental conditions for the SOA particles produced from α-pinene ozonolysis and photooxidation investigated in this study and previous studies. In this study, data on the average O : C values were not available; thus, we chose O : C values from the literature that were closest to the experimental conditions (Table S2). The O : C values for the SOA particles derived from α-pinene ozonolysis range from 0.42 to 0.44 as per Li et al. (2015), whereas those for SOA particles derived from α-pinene photooxidation are between 0.40 and 0.90 according to Lambe et al. (2015).

According to the dataset of average O : C values of different types of SOA particles from this study as well as previous studies, Fig. 6 shows that LLPS occurred when the average O : C was between 0.34 and 0.44. This range of the O : C required for the occurrence of LLPS in the SOA particles is consistent with those from previous studies (Renbaum-Wolff et al., 2016; Rastak et al., 2017; Song et al., 2017). However, LLPS did not occur when the average O : C was between 0.45 and 1.30 in this study. Using a new type of SOA particle generated from α-pinene photooxidation, we showed that the absence of LLPS occurs over a wider range of O : C values than reported by a previous work (0.52–1.30; Song et al., 2017).

Similar to the results for LLPS in the SOA particles with respect to the O : C, bulk solutions containing two organics and water also showed the miscibility gap (Ganbavale et al., 2015). For example, bulk solutions of two organics with a low O : C and water (e.g., a mixture of 1-butanol, 1-propanol and water) formed two liquid phases (Ganbavale et al., 2015). However, bulk solutions of two organics with a high O : C
and water (e.g., a mixture of ethanol, acetic acid and water) formed a single liquid phase.

Previous studies have found nitrogen-containing SOA species in the presence of NH₃ (Laskin et al., 2015; Y. Liu et al., 2015). These studies suggested that ammonium carboxylates were formed by neutralization between carboxylic acid and ammonia, and that amines were formed by carbonyl and ammonia via a Schiff base reaction (Na et al., 2006, 2007; Laskin et al., 2015). The nitrogen to carbon (N : C) ratio was reported to be 0.01–0.08 based on aerosol mass spectrometry (AMS) and Fourier transform ion cyclotron resonance (FT-ICR MS) (Laskin et al., 2014; Y. Liu et al., 2015). It is noteworthy that ammonium carboxylates and amines are highly water soluble compounds. However, more accurate data regarding O : C values of SOA particles in the presence of NH₃ are needed.

Figure 6 also showed the range of the two liquid phases. The two phases consisting of an organic-rich shell and water-rich core were observed at RH values as high as ∼ 100 % in all cases. Recent studies by Rastak et al. (2017) and Liu et al. (2018) showed, using laboratory work and modeling results, that the presence of LLPS in organic particles at ∼ 100 % RH can lead to lower surface tension, and finally a lower kinetic barrier to CCN activation. Our result can also provide additional insight into attempting more accurate predictions of the CCN properties of organic particles (Petters et al., 2006; Hodas et al., 2016; Renbaum-Wolff et al., 2016; Ovadnevaite et al., 2017; Rastak et al., 2017; Liu et al., 2018).

4 Summary

In this study, we investigated liquid–liquid phase separation of SOA produced from both α-pinene ozonolysis and α-pinene photooxidation in the presence or absence of NH₃. We conducted humidity cycles at a temperature of 289 ± 0.2 K for four different SOA particles derived from α-pinene ozonolysis, α-pinene photooxidation, α-pinene ozonolysis with NH₃ and α-pinene photooxidation with NH₃, for particle mass concentrations of ∼ 500–1000 µg m⁻³. Among the four different types of SOA particles, LLPS occurred in SOA particles produced from α-pinene ozonolysis at 95.8 ± 2.3 % RH with increasing RH and in those produced from α-pinene ozonolysis with NH₃ at 95.4 ± 2.9 % RH with increasing RH. In both types of particles, the two liquid phases coexisted up to ∼ 100 % RH. However, LLPS was not observed in SOA particles produced from α-pinene photooxidation and α-pinene photooxidation with NH₃. LLPS occurred in the SOA particles produced by α-pinene ozonolysis, whereas no LLPS was observed in the SOA particles produced by α-pinene photooxidation. In addition, the occurrence of LLPS did not depend on the presence or absence of NH₃. Analysis of the dataset of the average O : C values of different types of SOA particles from this study and those from previous studies indicated that LLPS occurred when the O : C was less than ∼ 0.44, and LLPS did not occur when the O : C was greater than ∼ 0.40.

Considering the range of the O : C values of organic particles in the atmosphere (0.2–1.0), these results provide addi-
tional evidence that LLPS can occur in organic particles even without the presence of inorganic salts in the atmosphere. Moreover, LLPS occurred in the SOA particles at high RH values (as high as \( \sim 100\% \)), implying that these results can provide additional information regarding the CCN properties of organic particles. Additional studies are needed to confirm LLPS in SOA particles produced using more atmospherically relevant VOC mass concentrations, particle mass concentrations and submicron sizes.
