**Abstract.** Atmospheric brown carbon (BrC) plays significant roles in the light absorption and photochemistry of the atmosphere. Although the sources and occurrences of BrC have been studied extensively, its removal processes and optical characteristics in the atmosphere have been poorly understood. In this study, we examined the seasonal changes in sources and sinks of BrC and water-soluble organic carbon (WSOC) in the atmosphere of Seoul, South Korea. Our results showed that the concentrations of BrC and WSOC decreased by approximately 80% and 30%, respectively, from the cold season (October–January) to the warm season (June–September). Excitation–emission matrix (EEM) spectra showed that the humic-like substance (HULIS) was the dominant fraction of BrC as the other components were not measurable. The air mass back trajectories of fire burning practices and the variations in non-crustal potassium (K) and vanadium (V) contents in the water-soluble aerosols during all seasons showed no measurable decrease in input of biomass-burning sources in summer. However, there was a significant shift in photo-resistivity of light-absorbing organic aerosols in the summer, indicating larger removals of ultraviolet (UV) degradable BrC. This trend is supported by laboratory UV radiation experiments on the optical property changes of BrC and WSOC in aerosol samples. Thus, our results suggest that the photodegradation has dominant roles in controlling the quantity and quality of light-absorbing organic aerosols in the different seasons in the midlatitude atmosphere.

## 1 Introduction

Organic aerosols play a significant role in atmospheric chemistry and the global climate system (Ghan and Schwartz, 2007; Duarte and Duarte, 2013; Kirillova et al., 2014a). Most organic aerosols consist of a significant fraction of carbonaceous organic aerosols absorbing radiation (Laskin et al., 2015). These light-absorbing organic aerosols, referred to as brown carbon (BrC), have attracted increasing attention owing to their significant roles in the radiative forcing of the global climate system by directly absorbing solar radiation (Andreae and Gelencsér, 2006; Graber and Rudich, 2006; Ramanathan et al., 2007; Kirillova et al., 2014a; Saleh et al., 2014) and indirectly acting as cloud condensation nuclei (CCN) for cloud formation (Kanakidou et al., 2005; Andreae and Gelencsér, 2006; Graber and Rudich, 2006; Kirillova et al., 2014a). The light-absorbing property of BrC, which absorbs solar radiation in the range of ultraviolet (UV) to visible wavelengths, is expected to be considerably weaker than that of the black carbon (BC), which absorbs over a wide spectral range from UV to near-infrared radiation (Feng et al., 2013; Laskin et al., 2015). However, its contribution would be significant due to its higher abundances over source regions (Hoffer et al., 2006; Gustafsson et al., 2009; Feng et al., 2013). Previous studies have estimated that the BrC contributes to approximately 19% of the total atmospheric radiative forcing (Feng et al., 2013).

The origin of BrC is attributed predominantly to the atmospheric humic-like substance (HULIS), which has properties similar to terrestrial and aquatic humic and fulvic acids (Andreae and Gelencsér, 2006; Graber and Rudich, 2006; Lukács et al., 2007; Laskin et al., 2015; Yan and Kim, 2017). Previ-

ous studies have identified that HULIS has both direct emission sources from biomass burning, marine aerosols, and soil resuspension and indirect contribution from secondary formation (Graber and Rudich, 2006; Hoffer et al., 2006; Lin et al., 2010; Yan and Kim, 2017). Recently, residential coal combustion was suggested as an important source of HULIS during cold seasons (Tan et al., 2016; Voliotis et al., 2017; Li et al., 2019). Besides HULIS, biological aerosols (e.g., bacteria, algae, pollen, spores, fungi, plant debris, and animal tissue) are another important sources of BrC (Després et al., 2012; Pöhlker et al., 2012). In general, the atmospheric HULIS contributes to approximately 70 % of the water-soluble organic carbon (WSOC) (Laskin et al., 2015; Park and Son, 2017), while the WSOC contributes to 10 %–80 % of the total organic carbon contents in aerosols (Kirillova et al., 2014a, b; Fu et al., 2015). However, current understanding of the optical properties, chemical compositions, and degradation processes of light-absorbing organic aerosols still remain uncertain.

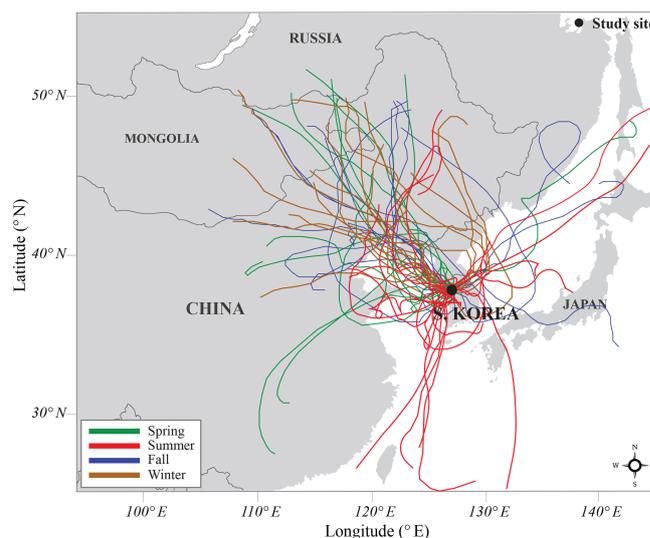

In this study, we evaluated the seasonal changes in optical and chemical characteristics, including photo-resistivity, of light-absorbing organic aerosols in an urban region. Recently, the method of excitation–emission matrix (EEM) characterization combined with a parallel factor analysis (PARAFAC) model has been employed for BrC studies (Kieber et al., 2006; Mladenov et al., 2011; Matos et al., 2015; Chen et al., 2016; Yan and Kim, 2017). This unique multi-analysis method can be used to identify individual chromophores of aerosol samples (i.e., HULIS versus protein-like substance) and light-absorbing properties of each sample. In addition, the stable carbon isotope ratios of WSOC ( $\delta^{13}\text{C}_{\text{WSOC}}$ ) and various chemical constituents were measured to identify the potential sources of organic aerosols in different seasons. Furthermore, we conducted laboratory experiments on the direct photochemical degradations of aerosol samples to verify the impacts of the UV radiation on the optical properties and carbon compositions of BrC and WSOC in the atmosphere.

## 2 Experimental methods

### 2.1 Study site and sample collection

Seoul is the capital city of South Korea and one of the largest metropolitan cities in the world. Korea has been highly affected by severe dust storms known as Asian dust or the yellow dust originating from the Chinese and Mongolian deserts during the spring (March–May) and often during the winter (December–January) (Lin et al., 2012). The increase in contents of fine aerosols associated with anthropogenic emissions is of great concern and a focus of major environmental studies in this region (Seinfeld et al., 2004; Park et al., 2007).

Aerosol samples ( $N = 78$ ) were collected using a high-volume air sampler (HV-1000, SHIBATA) from March 2015

**Figure 1.** Map of the geographical region around the study site and air mass transport pathways in the different seasons: spring (green), summer (red), fall (blue), and winter (brown). The 10 d air mass back trajectory was drawn by using the HYSPLIT model from March 2015 to January 2016 in Seoul, South Korea.

to January 2016 in Seoul, South Korea (37.5° N, 127.0° E; 20 m above ground level) (Fig. 1). The samples were collected for 24 h at a constant flow rate of 1000 L min<sup>-1</sup> through a pre-combusted (450 °C for 5 h) glass microfiber filter (GF/F, 8 × 10 inch, 2 μm pore size, Whatman). A blank sample was collected by shortly exposing a blank filter at the study site and analyzed in the same manner as that for the other samples. The total suspended particulates (TSPs) of the aerosol samples were measured by using the mass differences in desiccated filters between the pre- and post-sampling. The collected samples were covered with an aluminum foil, placed in a polyethylene bag, and stored in the dark at -20 °C.

Meteorological parameters of the study site including the temperature and UV radiation rate were obtained from the ambient air quality monitoring network named AirKorea in the Korea Environmental Corporation (KECO) and Korea Meteorological Administration (KMA). Fire maps around the study site were obtained by using the Moderate Resolution Imaging Spectroradiometer (MODIS) fire location data provided by NASA's Fire Information for Resource Management System (FIRMS) (Fig. S1 in the Supplement).

A 10 d air mass back trajectory was drawn by using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model to determine the source regions and transport pathways of air masses to the study site (Stein et al., 2015) (Fig. 1). Due to a regional meteorology of the study site, which is dominated by the East Asian monsoonal effect, most air masses are transported from the arid and semiarid regions in the Asian continent for most of the year (Yan and Kim, 2012, 2017).

## 2.2 Aerosol extraction and chemical analyses

For the analyses of water-soluble organic aerosols, a small portion of filter paper was cut into small pieces and placed in a pre-HCl-rinsed bottle. The organic components in the sample were extracted using Milli-Q water (18.2 M $\Omega$  cm) shaken at 125 rpm for 4 h (Wozniak et al., 2012). Then, the extracts were filtered through a syringe filter (0.45  $\mu$ m pore size Nucleopore, Whatman) and analyzed to evaluate the WSOC and total dissolved nitrogen (TDN) by a high-temperature oxidation method using a total organic carbon (TOC) analyzer (TOC-V<sub>CPH</sub>, Shimadzu). The major ion species (NO<sub>x</sub>, NH<sub>4</sub><sup>+</sup>, SO<sub>4</sub><sup>2-</sup>, Ca<sup>2+</sup>, Cl<sup>-</sup>, Na<sup>+</sup>, and K<sup>+</sup>) were analyzed by using a high-performance liquid chromatography (HPLC) (Waters 2695) system equipped with a conductivity detector (Waters 432) (Yan and Kim, 2015). The subsamples for trace element analyses were acidified to 2 % ultra-pure HNO<sub>3</sub> and analyzed by using a high-resolution inductively coupled plasma mass spectrometer (HR-ICP-MS) (Thermo Element 2). In order to correct the instrumental instability, Rh was included as internal standard. The molecular marker compound, levoglucosan, was measured by using a gas-chromatography–mass spectrometry (GC-MS) (7890N, Agilent) system coupled with a fused silica capillary column (HP-5MS, 25 m length, 0.25 mm i.d. and film thickness of 0.10  $\mu$ m). Monthly representative filter samples were used for the analysis ( $N = 25$ ). The water-soluble organic nitrogen (WSON) concentration was calculated by using the concentration difference between the TDN and sum of inorganic nitrogen species (NO<sub>2</sub><sup>-</sup>, NO<sub>3</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup>).

The non-crustal potassium (K) and vanadium (V) fractions were estimated by using the following equation (Yan and Kim, 2012):

$$[\text{non-crustal } X] = [X] - ([X]/[\text{Al}])_{\text{crust}} \times [\text{Al}]_{\text{aerosol}}. \quad (1)$$

For these calculations, the element compositions of the upper continental crust for K, Al, and V are assumed to be 2.80, 8.04, and 0.006 wt. %, respectively (Taylor and McLennan, 1995). The sea-spray fraction was estimated by using Cl<sup>-</sup> and Na<sup>+</sup> concentrations assuming that all Cl<sup>-</sup> and Na<sup>+</sup> originate from seawater: sea spray = Cl<sup>-</sup> + 1.4486 Na<sup>+</sup> (Maenhaut et al., 2007).

The value of  $\delta^{13}\text{C}_{\text{WSOC}}$  was measured by using an isotope ratio mass spectrometer (IRMS) (Isoprime, Elementar) combined with a TOC analyzer (Vario TOC cube, Elementar) (Panetta et al., 2008; Troyer et al., 2010; Kim et al., 2015; Yan and Kim, 2017). The isotopic composition  $\delta^{13}\text{C}_{\text{WSOC}}$  was determined using the following equation:

$$\delta^{13}\text{C} = \left( \frac{(^{13}\text{C}/^{12}\text{C})_{\text{Sample}}}{(^{13}\text{C}/^{12}\text{C})_{\text{Standard}}} - 1 \right) \times 1000\text{‰}, \quad (2)$$

where Vienna Pee Dee Belemnite (VPDB) was used as the isotope standard (Kelly et al., 2005; Troyer et al., 2010; Fu

et al., 2015). Analytical tests were made with IAEA-CH6 sucrose ( $\delta^{13}\text{C} = -10.45 \pm 0.03\text{‰}$ ) and Suwannee River Fulvic Acid (SRFA) ( $\delta^{13}\text{C} = -27.6 \pm 0.12\text{‰}$ ; International Humic Substances Society) to evaluate the recovery and the accuracy of the measurements (Panetta et al., 2008; Troyer et al., 2010).

The HULIS fraction was separated by solid-phase extraction (SPE) by using DEAE column (GE Healthcare<sup>®</sup>, HiTrap<sup>™</sup> DEAE FF, 0.7 cm ID  $\times$  2.5 cm) to validate the humic fraction obtained by using the EEM-PARAFAC results (Baduel et al., 2009). The sample solutions were passed through the column at a constant flow rate of 1.0 mL min<sup>-1</sup>. The neutral components and hydrophobic bases, mono- and di-carboxylic acids, and inorganic anions were removed with Milli-Q water and 0.04 M NaOH. The polycharged compounds, HULISs, were eluted with 1 M NaCl. The final fractions were analyzed for the HULIS quantification using a TOC analyzer.

## 2.3 Fluorescence and absorbance measurements

Fluorescence EEM and absorbance spectra of the aerosol samples were measured by using a spectrophotometer (Aqualog, Horiba). The emission and excitation wavelength ranges were 240 to 700 and 250 to 500 nm, respectively, with scanning intervals of 1 nm. The PARAFAC model was performed using the Solo software in order to determine the different fluorescent components in aerosol samples. The results were validated by split-half analysis and random initialization (Bro, 1997; Zepp et al., 2004; Stedmon and Bro, 2008). The Raman and Rayleigh scattering signals, inner-filter effect, and blank subtraction were corrected using the Solo software. The fluorescence intensity was normalized by Raman peak area of water and stated as Raman unit (RU) (Lawaetz and Stedmon, 2009). This is a simple calibration method for quantitative fluorescence spectroscopy using the integrated area of water Raman peak at an excitation wavelength of 350 nm (Lawaetz and Stedmon, 2009).

The absorption coefficient was calculated using the following equation:

$$\alpha = 2.303A/l, \quad (3)$$

where  $a$  is the absorption coefficient (m<sup>-1</sup>);  $A$  is the absorbance;  $l$  is the optical path length of the quartz cuvette (m). The spectral slope ( $S$ ) was calculated using following equation:

$$a_{\lambda} = a_{\lambda_{\text{ref}}} e^{-S(\lambda - \lambda_{\text{ref}})}, \quad (4)$$

where  $a$  is the Napierian absorption coefficient (m<sup>-1</sup>);  $\lambda$  is the wavelength;  $\lambda_{\text{ref}}$  is the reference wavelength (Twardowski et al., 2004; Helms et al., 2008). In this study, two distinct spectral ranges were selected in the shorter wavelength (275–295 nm) and the longer wavelength (350–400 nm).

## 2.4 Photochemical degradation experiments for light-absorbing organic aerosols

Laboratory experiments were conducted for two different durations (12 h and 42 d) using a small portion of the aerosol filter samples inside of the incubator equipped with an internal UV lamp (UV-B; 280–315 nm; 15 W). The filter samples for the experiment were duplicated or triplicated to rule out any experimental bias. The incubator was maintained under positive air pressure with a constant temperature at 20 °C. Aerosol samples were directly exposed to the UV radiation as its original particulate form, and each of the non-irradiated aerosol samples was evaluated for the initial conditions. For a long-term test, two representative aerosol filter samples were randomly selected from each of the higher and lower fluorescent groups, which had a similar range of WSOC concentration (winter = 19  $\mu\text{M}$ ; summer = 16  $\mu\text{M}$ ). After the UV irradiation, filter samples were completely covered to prevent exposure to any light. The extraction of organic components was performed using the same procedure as described above. Each sample was analyzed for optical and chemical properties after the irradiation.

## 3 Results

### 3.1 BrC compositions

The PARAFAC model identified two humic-like fluorescent components and one protein-like fluorescent component (Fig. S2). The spectral characteristics of component 1 (C1; Ex / Em = 305/416 nm) and component 3 (C3; Ex / Em = 365/484 nm) are known to be highly associated with the atmospheric HULIS (Chen et al., 2016; Yan and Kim, 2017). Component 2 (C2; Ex / Em = 290/340 nm) is associated with a protein-like (tryptophan-like) component, which originates mostly from biological production (Coble, 2007; Birdwell and Engel, 2010; Yan and Kim, 2017) (Supplement Table S1). However, C2 seems to be largely influenced by the dominant fluorophore HULIS, as shown by the EEM spectra (Fig. S7). A good correlation between C1 and C2 ( $r^2 = 0.9$ ;  $p < 0.05$ ) was obtained, although, in general, these two components have different sources and sinks in the atmosphere (Yan and Kim, 2017) (Fig. S3). Thus, we assumed that the HULIS (C1 and C3) was the dominant component of BrC in these samples, and C1 was used as a representative component of BrC in this study, as C1 and C3 exhibited a good correlation ( $r^2 = 0.8$ ;  $p < 0.05$ ) (Fig. S3).

The HULIS component obtained by the EEM-PARAFAC model agreed very well with the extracted HULIS concentration obtained by using the DEAE column ( $r^2 = 0.81$ ;  $p < 0.05$ ), indicating that the C1 component represents the actual HULIS (Fig. S4). In addition, we compared the extraction efficiencies of HULIS (water-soluble BrC) with that of the MeOH-soluble BrC (Fig. S4). Although the efficiency

of the water-soluble BrC was approximately 20 % lower than that of the MeOH-soluble BrC, they exhibited a good correlation ( $r^2 = 0.9$ ;  $p < 0.05$ ) (Fig. S4b). Therefore, we conclude that the HULIS is a good representative component of BrC in this study.

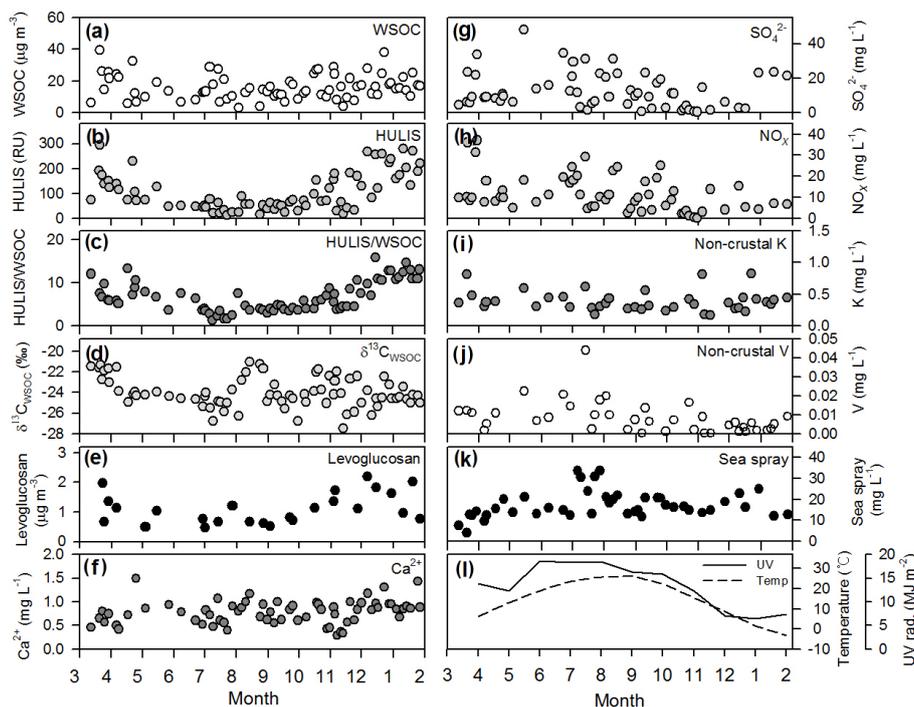

### 3.2 Seasonal variations in BrC and WSOC

The WSOC concentrations exhibited seasonal variations in the range of 3 to 40  $\mu\text{g m}^{-3}$  (average =  $16 \pm 7 \mu\text{g m}^{-3}$ ) with higher values during the cold seasons (October–January) (average =  $18 \pm 7 \mu\text{g m}^{-3}$ ) and lower values during the warm seasons (June–September) (average =  $13 \pm 3 \mu\text{g m}^{-3}$ ) (Fig. 2a). Similarly, the HULIS concentrations exhibited seasonal variations in the range of 13 to 294 RU (average =  $108 \pm 77 \text{RU}$ ) with higher values during the cold seasons (average =  $152 \pm 76 \text{RU}$ ) and lower values during the warm seasons (average =  $46 \pm 20 \text{RU}$ ) (Fig. 2b). After the HULIS content was normalized to the WSOC contents, the seasonal trend of the ratio of the HULIS content to the WSOC content was similar to that of the HULIS concentration indicating that there was a pronounced decrease in the average fraction of HULIS relative to WSOC from the cold to the warm seasons (Fig. 2c).

The  $\delta^{13}\text{C}_{\text{WSOC}}$  values ranged from  $-21.0\text{‰}$  to  $-27.5\text{‰}$  (average =  $-24.0 \pm 1.5\text{‰}$ ), with no such seasonal variation trend (Fig. 2d). The levoglucosan concentration was in the range of 0.5 to 2.2  $\mu\text{g m}^{-3}$  (average =  $1.1 \pm 0.5 \mu\text{g m}^{-3}$ ) with relatively higher values during the cold seasons and the lower values during August–September (Fig. 2e). The temporal variations in major ion species concentrations did not show such seasonal behaviors throughout the year (Fig. 2f–k). The temporal variation in  $\text{Ca}^{2+}$  concentration (average =  $0.8 \pm 0.2 \text{mg L}^{-1}$ ) exhibited a relatively constant level throughout the year (Fig. 2f). The  $\text{SO}_4^{2-}$  concentrations (average =  $12.0 \pm 10.3 \text{mg L}^{-1}$ ) exhibited the highest value during the period of spring to summer and were slightly decreased during the cold seasons (Fig. 2g). The concentration of  $\text{NO}_x$  (average =  $11.7 \pm 8.7 \text{mg L}^{-1}$ ) was high during the warm periods (June–October) (Fig. 2h). The concentration of non-crystal K (average =  $0.4 \pm 0.2 \text{mg L}^{-1}$ ) also showed a relatively constant level throughout the year (Fig. 2i). The non-crystal V concentrations (average =  $0.01 \pm 0.01 \text{mg L}^{-1}$ ) showed no such seasonal variations (Fig. 2j). The sea-spray concentrations ranged from 4.0 to 33.6  $\text{mg L}^{-1}$  (average =  $17.3 \pm 6.4 \text{mg L}^{-1}$ ), showing the highest concentration in July (Fig. 2k). Both temperature and UV radiation rate showed the typical patterns of middle latitudes (Fig. 2l).

## 4 Discussion

In order to characterize the sources of HULIS and WSOC in Seoul, which may cause the seasonal variabilities, we analyzed various tracers including  $\delta^{13}\text{C}_{\text{WSOC}}$ , major ions, and

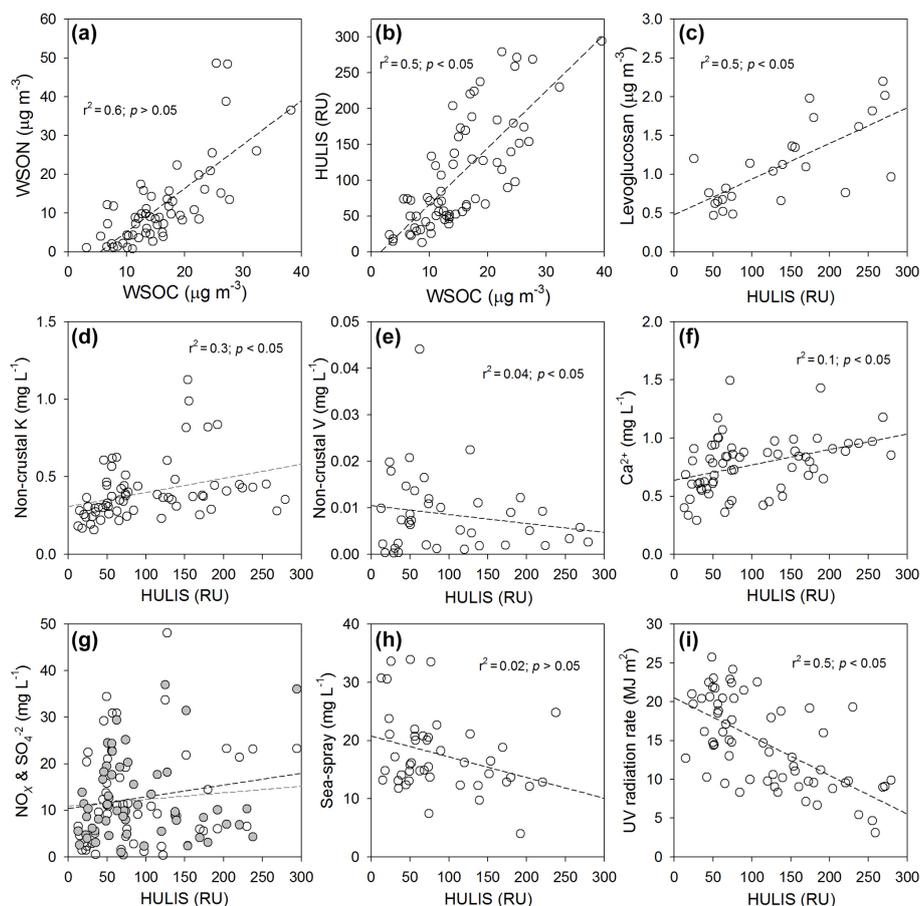

**Figure 2.** Temporal variations in (a) WSOC concentration, (b) fluorescence intensity of HULIS, (c) ratio of HULIS to WSOC, (d)  $\delta^{13}\text{C}_{\text{WSOC}}$  values, (e) levoglucosan, (f)  $\text{Ca}^{2+}$ , (g)  $\text{SO}_4^{2-}$ , (h)  $\text{NO}_x$ , (i) non-crystal K, (j) non-crystal V, (k) sea-spray concentrations, (l) UV radiation rate, and temperature from March 2015 to January 2016 in Seoul, South Korea.

molecular marker as source indicators (Gabriel et al., 2002; Kelly et al., 2005; Kirillova et al., 2014b; Fu et al., 2015; Yan and Kim, 2015). The average  $\delta^{13}\text{C}_{\text{WSOC}}$  ( $-24.0 \pm 1.5\text{‰}$ ) suggests that the burning activity of terrestrial C3 plant-origin materials (e.g., grassland, crop residue, fuel wood) could be a major source of WSOC in this region (Kelly et al., 2005; Das et al., 2010; Kawashima and Haneishi, 2012; Fu et al., 2015). The average  $\delta^{13}\text{C}_{\text{WSOC}}$  was in good agreement with that of HULIS ( $-25.4 \pm 1.6\text{‰}$ ) extracted from precipitation in Seoul, South Korea (Yan and Kim, 2017).

The good correlation ( $r^2 = 0.6$ ;  $p > 0.05$ ) between the WSOC and WSON concentrations suggests that these two variables are highly associated with a common organic source (Yan and Kim, 2015) (Fig. 3a). The WSOC and HULIS concentrations also exhibited a good correlation ( $r^2 = 0.5$ ;  $p < 0.05$ ) (Fig. 3b). A good linear correlation ( $r^2 = 0.5$ ;  $p < 0.05$ ) was also observed between the HULIS and levoglucosan concentrations (Fig. 3c). This relationship indicates that biomass burning is a significant source of HULIS in Seoul, as levoglucosan is commonly used for the tracing of biomass burning (Fu et al., 2015; Kuang et al., 2015). This is consistent with the previous study, which has demonstrated that the BrC in the precipitation was primarily derived from biomass burning and terrestrial biogenic emissions ( $> 70\%$ ), with minor contributions from fossil-fuel combustion, based on the  $^{14}\text{C}$  values in the HULIS (Yan and Kim, 2017). However, we observed significant decreases

( $35 \pm 2\%$ ) in levoglucosan concentrations by the UV irradiation for 12 to 24 h in the laboratory experiments (Fig. S5). This is consistent with the previous studies showing that levoglucosan could be oxidized by the hydroxyl radical in the atmosphere (Hennigan et al., 2010; Hoffmann et al., 2010). Thus, we suggest that the major source of HULIS in our samples was from biomass burning, but low concentrations in WSOC and HULIS in summer could not be evaluated by using the levoglucosan.

In order to indirectly evaluate the biomass burning during the study period, we compiled the fire maps in combination with air mass back trajectories (Fig. S1). An evidence for the biomass burning effect is provided by the fire maps, where higher occurrences of fire spots correspond to agricultural burning practices in the East Asia continental areas (Fig. S1). The burning practices mainly occurred in the spring and summer in the East Asia continental areas. No significant influence of open burning activity was observed in the winter (Fig. S1). These results suggest that the distinctive biomass burning was not linked to the seasonal variations in WSOC and HULIS concentrations in this study region. On the other hand, non-crystal K, which is an indicator of biomass or fossil fuel burning (Gabriel et al., 2002; Baduel et al., 2010), did not exhibit a seasonal trend (Fig. 2i). The correlation between the HULIS and non-crystal K was also insignificant ( $r^2 = 0.3$ ;  $p < 0.05$ ) (Fig. 3d). The K/V ratio is often used to trace V-purified fossil fuels, since V is mostly removed

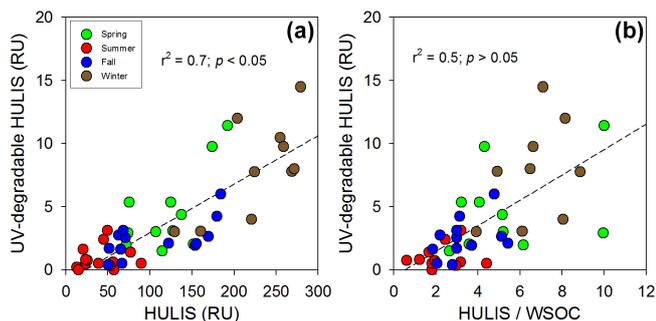

**Figure 3.** Plots of the concentrations of (a) WSOC versus WSON, (b) WSOC versus HULIS, (c) HULIS versus levoglucosan, (d) HULIS versus non-crystal K, (e) HULIS versus non-crystal V, (f) HULIS versus  $\text{Ca}^{2+}$ , (g) HULIS versus  $\text{NO}_x$  (closed circle;  $r^2 = 0.1$ ,  $p > 0.05$ ) and  $\text{SO}_4^{2-}$  (open circle;  $r^2 = 0.02$ ,  $p < 0.05$ ), (h) HULIS versus sea spray, and (i) HULIS versus UV radiation rate. The dashed lines represent the regression lines.

during the refining processes (Yan et al., 2012). The use of raw materials such as crude oil and coal could be the source of non-crystal V (Tsukuda et al., 2005; Yan and Kim, 2012). However, the correlation between HULIS and non-crystal V was also insignificant ( $r^2 = 0.04$ ;  $p < 0.05$ ) (Fig. 3e), with K/V ratios in the range of 17–673 (average =  $124 \pm 154$ ) in our samples. This result suggests that the V-purified fossil fuel contents in our samples were insignificant (Yan et al., 2012). No significant correlations were observed between the HULIS and  $\text{Ca}^{2+}$  ( $r^2 = 0.1$ ;  $p < 0.05$ ),  $\text{NO}_x$  ( $r^2 = 0.1$ ;  $p > 0.05$ ),  $\text{SO}_4^{2-}$  ( $r^2 = 0.02$ ;  $p < 0.05$ ), and sea-spray fraction ( $r^2 = 0.02$ ;  $p > 0.05$ ) (Fig. 3f–h). This also indicates that the seasonal changes in HULIS concentrations were insignificantly influenced by crustal minerals, sea salts, and fossil fuels. All these tracers suggest that the summer decreases in WSOC and HULIS concentrations were not associated with the changes in source inputs.

A significant negative correlation ( $r^2 = 0.5$ ;  $p < 0.05$ ) was observed between HULIS and the UV radiation (Fig. 3i). The HULIS was greatly reduced during the warm seasons

(June–September) when the solar UV radiation and the temperature reached the annual maxima (Fig. 2b, l). It has been widely accepted that photochemical degradation is an important process for the efficient removal or alteration of photo-resistivity and compositions of chromophoric dissolved organic matter (CDOM) in rainwaters and aerosols (Kieber et al., 2006; Mladenov et al., 2009; Forrister et al., 2015; Dasari et al., 2019; Healy et al., 2019). Significant seasonal changes in ratios of the HULIS concentration to the WSOC concentration, although the WSOC and HULIS concentrations exhibited similar seasonal changes, also suggest that HULIS is more effectively removed by the UV radiation in summer (Fig. 2c). These results are in agreement with the following laboratory experimental results.

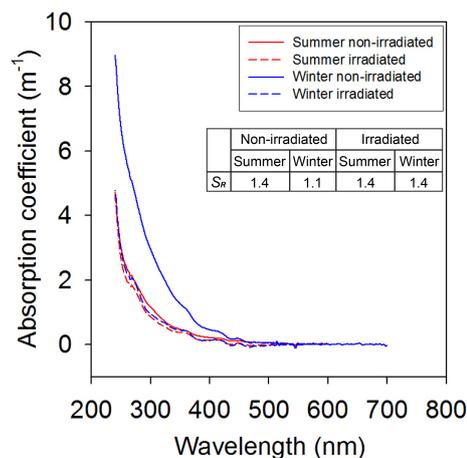

In order to quantify the UV-degradable HULIS, we performed the UV radiation experiments for the short term (12 h; 48 samples) and the long term (42 d; 2 samples). After the 12 h of UV irradiation, the HULIS concentrations in the winter samples (characterized by higher average HULIS concentrations;  $N = 35$ ) were greatly reduced by 13 % (Fig. 4a).

**Figure 4.** Plots of the (a) HULIS versus UV-degradable HULIS and the (b) ratio of HULIS to WSOC versus UV-degradable HULIS in the different seasons: spring (green), summer (red), fall (blue), and winter (brown). The dashed lines represent the regression lines.

Similar decreases were observed for the WSOC concentrations for the winter samples (Fig. 4b). However, negligible changes (< 2 %) were observed in the summer samples (characterized by low average HULIS concentrations,  $N = 13$ ) (Fig. 4a). After the 42 d of UV irradiation, the HULIS and WSOC concentrations in the winter sample decreased by approximately 52 % and 25 %, respectively (Figs. S6 and S7). However, there was no significant change in HULIS and WSOC concentrations in the summer sample (Figs. S6 and S7). This result suggests that the summer sample might consist largely of a photo-refractory WSOC pool owing to the high UV radiation, while the winter sample consisted largely of a photolabile WSOC.

The change in light-absorbing property of HULIS for the UV radiation experiment also exhibited a similar change with that of fluorescence property (Fig. 5). The absorption coefficient of the summer sample was not changed after the irradiation, while that of the winter sample exhibited an approximately 2-fold change (Fig. 5). The degradation of HULIS was considerably more effective at shorter wavelengths ( $S_{275-295}$ ), while no significant change was observed at longer wavelengths ( $S_{350-400}$ ), as expected from the fact that the absorption losses are higher in shorter wavelengths than the longer wavelengths (Del Vecchio and Blough, 2002). In order to look at the changes in light absorption property, the spectral slope ratios ( $S_R$ ) of shorter wavelength ( $S_{275-295}$ ) relative to longer wavelength ( $S_{350-400}$ ) were compared. In general, the  $S_R$  value increases with increasing irradiation (Del Vecchio and Blough, 2002; Helms et al., 2008). The  $S_R$  values of non-irradiated samples were 1.1 in the winter and 1.4 in the summer, and the irradiated samples were 1.4 in both winter and summer (Fig. 5). The  $S_R$  values of non-irradiated and irradiated samples in summer showed no measurable change during the UV experiment (Fig. 5). In addition, if the input of fresh HULIS is constant throughout the seasons,  $S_R$  should be constant. However,  $S_R$  values of non-irradiated samples were 1.1 in the winter and 1.4 in the summer (Fig. 5). The  $S_R$  value of the

**Figure 5.** The absorption coefficients of the aerosol samples collected in the winter (30 December) (blue) and summer (14 August) (red) in 2015. The solid lines represent the initial values for the non-irradiated samples, and the dashed lines represent the final values for the irradiated samples.

non-irradiated summer sample was similar to that of the irradiated winter sample (1.4) (Fig. 5). Thus, this suggests that the lower summer HULIS concentration was associated with the UV degradation rather than with the reduced source inputs.

## 5 Conclusions

The seasonal variations in optical and chemical properties of the HULIS and WSOC were monitored in different seasons in the urban region. The air mass back trajectories combined with the fire maps and various chemical analyses demonstrated that biomass burning is a significant source contributing to HULIS in all seasons in Seoul, South Korea. Our results suggest that photo-induced degradation plays a significant role in BrC quantity and quality in the atmosphere. In addition, the important role of photochemical degradation as a removal mechanism was supported by the laboratory experiments. This may provide important pieces of evidence regarding the hidden life cycle of light-absorbing organic aerosols in the atmosphere.

The light-absorbing organic aerosols are considerably associated with climate sensitivity owing to their significant roles in the radiative forcing and global climate balance. Thus, this photochemical process needs to be considered in the modeling of climate forcing and biogeochemical cycles of the Earth's surface. Furthermore, the deposition fluxes of organic aerosols with different optical and chemical characteristics can have significant impacts as potential sources of organic carbon on surface waters and soils, which can lead to major effects on the global carbon cycle.
