Abstract. Tropospheric NO₂ column retrievals from the Global Ozone Monitoring Experiment (GOME) satellite spectrometer are used to quantify the source strength and 3-D distribution of lightning produced nitrogen oxides (NO_x=NO+NO₂). A sharp increase of NO₂ is observed at convective cloud tops with increasing cloud top height, consistent with a power-law behaviour with power 5±2. Convective production of clouds with the same cloud height are found to produce NO₂ with a ratio 1.6/1 for continents compared to oceans. This relation between cloud properties and NO₂ is used to construct a 10:30 local time global lightning NO₂ production map for 1997. An extensive statistical comparison is conducted to investigate the capability of the TM3 chemistry transport model to reproduce observed patterns of lightning NO₂ in time and space. This comparison uses the averaging kernel to relate modelled profiles of NO₂ to observed NO₂ columns. It exploits a masking scheme to minimise the interference of other NO_x sources on the observed total columns. Simulations are performed with two lightning parameterizations, one relating convective precipitation (CP scheme) to lightning flash distributions, and the other relating the fifth power of the cloud top height (H5 scheme) to lightning distributions. The satellite-retrieved NO₂ fields show significant correlations with the simulated lightning contribution to the NO₂ concentrations for both parameterizations. Over tropical continents modelled lightning NO₂ shows remarkable quantitative agreement with observations. Over the oceans however, the two model lightning parameterizations overestimate the retrieved NO₂ attributed to lightning. Possible explanations for these overestimations are discussed. The ratio between satellite-retrieved NO₂ and modelled lightning NO₂ is used to rescale the original modelled lightning NO_x production. Eight estimates of the lightning NO_x production in 1997 are obtained from spatial and temporal corre-

lation methods, from cloud-free and cloud-covered observations, and from two different lightning parameterizations. Accounting for a wide variety of random and possible systematic errors, we estimate the global NO_x production from lightning to be in the range 1.1–6.4 Tg N in 1997.

1 Introduction

Lightning produces substantial amounts of atmospheric nitrogen oxides (NO_x=NO+NO₂), key species that control the formation of tropospheric ozone (e.g. Crutzen, 1970) and influence the oxidising capacity of the troposphere (e.g. Labrador et al., 2004a). However, recent estimates of the annual global lightning NO_x production range from 0.9 to 13.2 Tg N, and the reported uncertainties of individual estimates have comparable magnitudes (see Table 1 for an overview). The ozone budget in the upper troposphere (UT) is strongly influenced by NO_x and reliable estimates of the global lightning-produced NO_x (hereafter LNO_x) budget are important for accurate knowledge of ozone in the UT where it is an efficient greenhouse gas. Appropriate quantification of the LNO_x budget is also important for estimating the lifetime of long-lived greenhouse gases such as methane, whose lifetime is determined by the OH concentration. Furthermore, the current level of uncertainty in LNO_x is hampering quantitative assessments of NO_x concentrations resulting from emissions by other sources such as industry and transport, biomass burning, soils and aircraft (Olivier et al., 2001).

Most estimates of the annual LNO_x budget published so far (Table 1) have modelled LNO_x in a “bottom-up” way. Bottom-up methods generally count the number of lightning flashes and make assumptions on lightning characteristics – like NO_x production efficiency per flash, energy ratio of cloud-to-ground (CG) to intra-cloud (IC) flashes – with only limited observational constraints (e.g. Nesbitt et al., 2000; Price et al., 1997a) to estimate the total LNO_x production.

Until recently there was lack of space observations and fundamental difficulties exist in extrapolating local in-situ (Levy et al., 1996) or regional (Beirle et al., 2004) observations to the global scale. Satellite measurements have the potential to solve this issue since global tropospheric columns of NO₂ from GOME have become available (e.g. Leue et al., 2001; Richter and Burrows, 2002; Martin et al., 2002; Boersma et al., 2004). Measurements by GOME are sensitive to tracers residing in the middle and upper troposphere such as NO_x from lightning. However, the LNO_x contribution to the total observed column is at most 10%, which severely complicates the discrimination of the lightning contribution from other tropospheric sources, the stratospheric background, and the measurement noise.

Several examples of enhanced NO₂ near thunderstorm complexes have been reported based on the GOME observations (e.g. Choi et al., 2005). Beirle et al. (2004) found a good correlation between monthly mean satellite measurements of tropospheric NO₂ columns and monthly mean lightning flash distributions measured by the Lightning Image Sensor (LIS) over Australia. Hild et al. (2002) demonstrated that GOME is sensitive to LNO_x deposited in a thunderstorm cloud. Apart from information on trace gases, GOME spectra also contain information on cloud fraction and cloud top altitude which is crucial for the LNO_x study. In this paper we will extend the individual observations by presenting a statistical study of NO_x enhancements at high clouds, based on the FRESCO cloud retrieval scheme (Koelemeijer et al., 2001).

Furthermore, we reverse in this work the often used “bottom-up” approach to determine the annual LNO_x production by imposing constraints on distributions of modelled lightning NO₂ (hereafter LNO₂) in the tropics by satellite observations. Levy et al. (1996) compared tropospheric NO_x simulations with aircraft measurements of LNO_x over various isolated regions in the world. While their comparisons were necessarily based on a limited number of aircraft flights, we present an extensive statistical study of LNO_x based on a full year (1997) of contiguous tropical GOME observa-

tions. We focus on situations downwind of storm systems over areas relatively free from pollution to avoid (1) difficulties related to large contributions from urban and biomass burning NO_x emissions, (2) complexities related to the radiative transport and profile shape dependency over thunderstorm situations (Hild et al., 2002), and partly also to avoid (3) difficulties in extrapolating the 10:30 local time measurements to values representative for the whole day. Because of the large data set available we arrive at significant results despite the small signal to noise ratio.

This paper is organised as follows: Sect. 2 describes the GOME tropospheric NO₂ observations, and Sect. 3 gives observational evidence that GOME detects strongly enhanced LNO₂ in situations where high clouds are present. Sect. 4 describes a statistical method for the comparison of modelled LNO₂ and observed patterns of (lightning) NO₂ columns, the way to correct for interfering NO_x from other sources, and is followed by a discussion of the results. Sect. 5 shows annual mean modelled and GOME-derived LNO₂ distributions. In Sect. 6, we use the ratio between modelled and observed LNO₂ to provide a top-down estimate of the global LNO_x production in 1997, and discuss the various sources of error in our method.

2 GOME tropospheric NO₂ observations

In this study we use tropospheric NO₂ columns determined with the retrieval-assimilation-modelling approach as developed during the European Union GOA project. The retrieval is based on a set of slant column densities retrieved by the University of Heidelberg (Wagner et al., 1999; Wenig et al., 2004). These columns are assimilated with the TM3 chemistry-transport model. The analysed stratospheric NO_x model field obtained in this way is consistent with both the GOME observations and analysed stratospheric dynamics from the European Centre for Medium-Range Weather Forecasts (ECMWF) used to drive the model. A tropospheric air mass factor is used to convert the tropospheric slant column

density (total slant column – assimilated “stratospheric” slant column) into a tropospheric vertical column density. Radiative transfer modelling for air mass factor calculation accounts for viewing geometry, cloud coverage and cloud top pressure, surface albedo and a priori NO₂ profile shapes modelled with TM3 for the GOME pixel position and time. Cloud information is retrieved from the FRESKO algorithm (Koelemeijer et al., 2001) that uses the strength of the absorption in the O₂–A band (758–778 nm) to estimate an effective cloud top height. The effective cloud top altitude is a measure for how far light penetrated into the atmosphere. Because of penetration of the light into the cloud this effective altitude typically corresponds to a level below the physical cloud top. The “continuum” reflectance level around the O₂–A band is used to determine the cloud fraction. More details on the tropospheric NO₂ retrieval can be found in Boersma et al. (2004).

There are four important features that make these retrievals especially suitable for the LNO_x study: (1) The correction for the stratospheric background is performed with an assimilation approach that explicitly accounts for zonal variability in the stratospheric NO₂ column caused by stratospheric dynamics, (2) A detailed error propagation is carried out for each individual retrieval (Boersma et al., 2004). This fully accounts for all error sources in the retrieval method (i.e., errors in the slant column fitting, in estimating stratospheric NO₂, and errors in cloud and albedo information), (3) The averaging kernel (AK) (Eskes and Boersma, 2003) that is associated with every individual retrieval is part of the data product. The AK allows model-predicted profiles to be compared directly to satellite retrieved columns by removing the comparison’s dependence on the a priori assumed profile shape. The averaging kernels also allow a meaningful model-GOME comparison in cases of full or partial cloud cover. (4) Explicit information of cloud fraction and cloud top altitude is retrieved based on the FRESKO algorithm (Koelemeijer et al., 2001).

Up till now, there is little independent NO₂ profile data available to validate the tropospheric column retrievals. Also, nitrogen oxides in the boundary layer have a large spatial and temporal variability. A comparison with in situ aircraft observations reported by Martin et al. (2004) shows that, on average, uncollocated in situ aircraft measurements of tropospheric NO₂ are consistent with GOME retrievals as described by Martin et al. (2002). An extensive set of surface NO₂ measurements is available on a routine basis from operational networks in Europe and America. However, in order to relate these surface concentrations to the retrieved column abundances, additional information is needed on the vertical distribution of NO_x. A recent study by Blond et al. (2005)¹

shows good quantitative agreement of yearly-mean values and spatial patterns over Europe from measured and modelled (CHIMERE) surface concentrations of NO₂, as well as between modelled and retrieved (SCIAMACHY) columns of NO₂. These SCIAMACHY columns have been retrieved with the same approach as used in this work.

Aircraft measurements and cloud-resolved modelling have shown that a large fraction of the LNO_x is deposited in the UT and upper part of clouds (e.g. Ridley et al., 1994; Pickering et al., 1998). Figure 1 in Eskes and Boersma (2003) shows that even for scenes completely free of clouds the sensitivity to UT NO₂ is only slightly below typical stratospheric sensitivities. The situation for cloudy scenes is more complex as clouds can both increase and decrease the capability of GOME to detect a tropospheric NO₂ signal. Clouds below a NO₂ layer increase the effective albedo of the scene, thereby increasing the detected slant column. On the other hand, high clouds may (partly) screen the NO₂ column below, thereby decreasing the signal. The larger the cloud fraction the stronger the effects described above. Figure 1 illustrates the effects for a scenario in terms of cloud height, cloud fraction, the Tracer Model 3 (TM3, Dentener et al., 2003) predicted vertical NO₂ profile shape, and the corresponding averaging kernel (Eskes and Boersma, 2003). The two panels in Fig. 1 serve as an example of a scene with an effective cloud top altitude of ≈750 hPa and a cloud fraction of 0.26. The surface albedo was 0.05, solar zenith angle 5.8°, and viewing zenith angle 26.0° for this scene. The right panel shows the high sensitivity of GOME for NO₂ above the cloud. Note that NO₂ may be present just above 750 hPa,

while NO₂ below the cloud top is effectively invisible for GOME.

The uncertainties for individual GOME measurements (Boersma et al., 2004) in the Southern Hemisphere tropics are shown in Fig. 2. For retrieved columns with small values, the uncertainty is dominated by the combined error from the spectral fitting and from the stratospheric column estimate. For columns exceeding 0.5×10^{15} molec. cm⁻², the uncertainty grows due to increasing errors related to cloud fraction, albedo and profile shape. In this study, 95% of the encountered columns are between values of -0.7×10^{15} molec. cm⁻² and $+1.0 \times 10^{15}$ molec. cm⁻² and corresponding retrieval errors for individual GOME pixels are in the $[0.3\text{--}0.6] \times 10^{15}$ molec. cm⁻² range. The retrieval procedure subtracts an estimated stratospheric slant column from an observed total slant column, and hence occasionally small, negative tropospheric columns may occur, consistent with the error bars on the total and stratospheric column estimate. Both positive and negative values should be used in the analysis to avoid biases.

3 Detection of LNO₂

In this section we investigate the dependence of LNO_x production on cloud height, based on the cloud properties and NO₂ columns retrieved from the GOME observations. High clouds are known to be related to enhanced lightning activity and enhanced NO_x production. Price and Rind (1992) argue that the lightning activity is correlated with cloud top height, since both are largely determined by the up-draft intensity. For a range of simultaneous lightning and cloud top height observations, they derived a relationship where lightning activity is proportional to the fifth power

Fig. 3. Schematic illustration of photons sampling the upper part of a cloud (left) and how this process is modelled in FRESCO and NO₂ air mass factor calculations (right).

of the storm dimension – or cloud top – H , i.e. higher clouds are expected to have strong increases in lightning activity. Ushio et al. (2001) also found an exponential increase in satellite-observed lightning intensity as a function of satellite-observed cloud height.

Figure 3 schematically describes the retrieval approach when clouds are present: the left part shows how photons sample the upper parts of the cloud before they are scattered back, and the right part shows the simplified representation of cloud scattering in our cloud scheme. In the FRESCO cloud retrieval, a cloud is approximated as a Lambertian reflecting surface with an albedo of 0.8 and the effective cloud top height corresponds to the height the surface needs to be lifted in a radiative transfer model to best match the measured depth of the O₂–A band. This effective cloud top height is depicted as the lowest dotted line in the left panel of Fig. 3. The same Lambertian reflector model is used in the radiative transfer calculations for the NO₂ retrievals.

In situations of high clouds with strong lightning activity, a large fraction of the LNO_x ends up in the top and anvil (Ridley et al., 1996) of the cloud where GOME has an enhanced sensitivity to LNO_x. A radiative-transfer study by Hild et al. (2002) shows that even in the case of thick clouds GOME is able to detect NO_x present several kilometers below the cloud top, consistent with our own calculations. One source of error in the cloud height is the fact that the FRESCO cloud top height is retrieved from photons with wavelengths near 758–778 nm, and may be different from the penetration depth (effective cloud top height) of photons with wavelengths near 440 nm used in the NO₂ retrieval procedure. Nevertheless, we expect that this error is small as cloud particles have scattering characteristics that hardly depend on wavelength in the visible part of the spectrum.

For our study of the dependence of observed NO₂ columns on cloud height for cloudy scenes, we used GOME observations over tropical oceans and continents in the 40° S–5° N

area. This area is characterised by strong lightning activity and the influence of other sources of NO_x (see Sect. 4) is relatively small compared to the industrialized Northern Hemisphere. We consider the subset of GOME observations where the reflectance of the cloud-covered part of the scene exceeds 75% of the total measured reflectance. Ghost column difficulties occur in situations when clouds screen the lower part of the atmosphere and the retrieved total column comes to depend heavily on the assumptions on the lower, unseen part. To avoid these difficulties, the “above-cloud” part of the NO₂ column is retrieved by discarding the model predicted ghost column in the air mass factor ($M'_{tr}=N_s/N'_v$) calculation, with the corrected vertical column N'_v defined as:

$$N'_v = w \cdot (N_v - N_{v,ghost}) + (1 - w) \cdot N_v, \quad (1)$$

with N_v the total predicted vertical column (that is normally used in air mass factor calculations), $N_{v,ghost}$ the ghost column from the surface up to the effective cloud height, and w the cloud reflectance fraction. Note that the satellite thus measures the integral of NO₂ concentrations from the cloud top to the tropopause. All tropospheric above-cloud NO₂ columns were stored in 5 hPa cloud top pressure bins. The annual mean tropospheric NO₂ column was calculated only if there were more than 15 measurements in a bin.

The upper panel of Fig. 4 shows the annual mean tropospheric NO₂ columns for convective events over tropical oceans as a function of cloud top height and the lower panel shows the same for tropical continents. Tropical oceans/continents are defined as the three tropical ocean/continent regions shown in Fig. 10. The insets in both panels show a log-log plot of the same curve for cloud top pressures below 440 hPa (above circa 6.5 km). Clouds with tops below 6.5 km are assumed not to produce substantial amounts of lightning. The increase relative to a background – resulting from other sources of NO₂ – is consistent with a power law (see insets). The background is defined as the fixed, non-lightning integral of NO₂ from the cloud top to the top of the troposphere. The background is determined from all cloudy-sky situations in 1997 with cloud tops lower than 6.5 km. The solid line is a fit of the form $A+B H^C$ with H the cloud top height, A , B free coefficients and a power $C=4.6$ for tropical oceans, and $C=5.1$ for tropical continents. This power however is quite sensitive to assumptions about the (height-dependence of the) background, or coefficient A . From fits with different choices of A we arrive at a conservative error estimate on C of ± 2 for both tropical oceans and continents (Ushio et al., 2001). The dependence of the observed NO₂ on cloud height is surprisingly consistent with the power-law parameterization of LNO_x in CTMs (Price and Rind, 1992). However, the power-law relation that we found is one of many functions that may fit the increase of NO₂ with cloud height well, and this result should not be interpreted as a validation of the power-law parameterization of Price and Rind (1992).

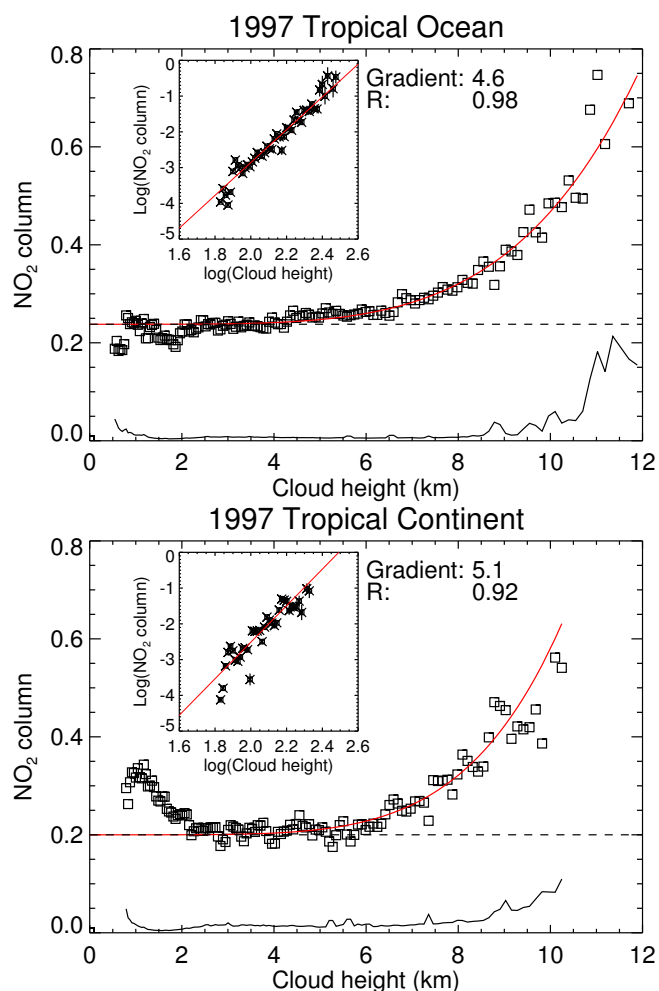

Fig. 4. The 1997-average of GOME observed near and above cloud top NO₂ column (unit 10^{15} molecules cm^{-2}) as a function of the cloud top height retrieved from GOME data with the FRESCO algorithm. The red curves represent the power-law fits. The dashed lines estimate the background due to other NO_x sources. The bottom solid lines represent the standard deviations of the mean NO₂ column per cloud-top pressure bin of 5 hPa. The top panel shows the cloud top dependency for tropical oceans, and the lower panel for tropical continents.

Often, the optical thickness of clouds is proportional to their geometrical thickness (Feigelson, 1984). Also, there may be transitions from mixed phase (supercooled droplets and ice) clouds to ice-only clouds at the -40°C level, so multiple scattering effects may change with cloud height. However, Hild et al. (2002) found that the air mass factor is hardly dependent on the cloud particle densities typical for thunderstorm clouds. We observe a continuous and large increase of tropospheric NO₂ for clouds higher than 6.5 km. It is unlikely that this observed increase would be the result of a strong change in cloud properties with altitude.

Fig. 5. The 1997 average of 10:30h lightning-produced above and near cloud top NO₂ columns as derived from GOME. Produced columns in 10¹⁵ molec. cm⁻².

The results in Fig. 4 allow us to derive a ratio of LNO_x production efficiencies of clouds over land and sea respectively. Fixing the power law coefficient C to 4.9 – a choice which is allowed within the error bars – we find that the production in terms of lightning NO₂ column density ($\times 10^{15}$ molec. cm⁻²) over continents equals $4.75 \cdot 10^{-6} H^{4.9}$, and over oceans $2.98 \cdot 10^{-6} H^{4.9}$. On average, we find that clouds of equal height produce $(4.75/2.98=)$ 1.6 times more LNO₂ over continents than over oceans at 10:30h local time (the overpass time of GOME). This ratio is not sensitive to details of our calculation (choice of background or difference between exponents), but is a direct measurement result. The size of the increase observed over high clouds is quite similar in absolute amount. For comparison, in TM3 a 24-h average ratio of 10 (Levy et al., 1996) is used, whereas for instance Michalon et al. (1999) derive a 24 h-average ratio of 5. Mesoscale convective systems over continents have a distinct minimum in convective activity at approximately 10:30 h and a strong maximum in the late afternoon whereas the diurnal cycle over the oceans is much weaker (Nesbitt and Zipser, 2002). Hence a ratio of 1.6 is most likely at the lower end of the 24-h cycle of convective intensity ratios.

The relation between cloud top height and LNO_x production allows us to produce a map of the global distribution of the 1997 average LNO₂ production at 10:30h. Application of the LNO₂ production parameterizations over continents ($4.75 \cdot 10^{-6} H^{4.9}$) and over oceans ($2.98 \cdot 10^{-6} H^{4.9}$) to all available FRESKO cloud height (H) data in 1997 results in Fig. 5. The most striking feature in Fig. 5 is the large average production of LNO₂ over tropical oceans relative to the small production over tropical continents. The observed patterns in Fig. 5 are representative for a 10:30h local time snapshot of convective activity: little convective activity and hence little lightning over continents is opposed to considerable activity over the tropical oceans.

Deriving quantitative NO₂ estimates from the observed cloud height dependence is difficult. The visible light detected by GOME samples only part of the cloud and the column above the cloud, as shown in Fig. 3. Quantitative estimates of the NO₂ column depend on assumed LNO_x profiles inside the cloud and cloud anvil, and on details of the light paths in the inhomogeneous cloud cover inside the large GOME footprint of 40×320 km². Moreover, a meaningful quantitative estimate of the NO₂ production requires scaling of the 10:30h local time observed production to values representative for 24-h averages. Also the large footprint of GOME of 320×40 km² as compared to typical sizes of convective cloud complexes complicates the interpretation of the results. Nevertheless, the rapid increase in observed NO₂ for high clouds strongly suggests that GOME is indeed capable of detecting LNO_x production.

4 Statistical comparison of observed NO₂ and modelled LNO₂

Apart from investigating above-cloud NO₂ columns as a function of cloud height, additional information on the NO₂ from lightning may be obtained from a comparison of modelled LNO₂ and observed NO₂ columns. We compare space and time-dependent patterns of observed NO₂ with modelled LNO₂ downwind of thunderstorms. First, the model and lightning parameterizations are introduced. Then, the comparison method is explained, followed by an introduction on a correction for the influence of NO_x from other sources. The section concludes with the results of the comparison and an interpretation of the results.

4.1 TM3 model and lightning parameterizations

The TM3 model, driven by 6-hourly meteorological analyses of the European Centre for Medium-Range Weather Forecasts (ECMWF), is a 3-D global chemistry-transport model that evaluates the NO₂ production by lightning and subsequent transport, chemical conversion, and the removal of NO₂ from the atmosphere. The model simulations are performed with a spatial resolution of 144×72 grid cells ($2.5^\circ \times 2.5^\circ$) and 31 σ hybrid-pressure levels from the surface up to 10 hPa. Recently the performance of TM3 was evaluated by comparing model simulations with aircraft observations from various aircraft campaigns (Meijer et al., 2000; Brunner et al., 2003, 2005).

TM3 has two parameterizations available for the calculation of lightning flashes and subsequent NO_x production, one based on convective precipitation (Meijer et al., 2001) (CP) and one based on a power-law (H5) parameterization (Price and Rind, 1992). Both schemes are described in more detail below.

4.1.1 Convective precipitation scheme

The CP scheme is motivated by the observed good correlation between convective precipitation and the number of lightning flashes (Meijer et al., 2001) over summertime Central Europe. Analysis of the National Lightning Detection Network (NLDN) data of the United States by Brunner and Van Velthoven (1999) also indicates a linear relationship of lightning with convective precipitation. Moreover the CP scheme showed good results between modelled NO_x concentrations and aircraft observations for situations downwind of thunderstorms (Meijer et al., 2001). To account for differences in convective regimes between continents and oceans, the CP scheme follows the recommendation by Levy et al. (1996) that deep convection over oceans is 10 times less efficient in generating lightning than deep moist convection over continents, due to much weaker vertical velocities in tropical clouds over oceans than over continents. The fraction of CG to the total number of flashes (CG+intra-cloud (IC)) is determined by a 4th order polynomial fit of the thickness of the (ECMWF) cloud above 0°C as proposed by Price and Rind (1993). CG strokes are assumed to be 10 times more energetic than IC strokes following Price et al. (1997a), although a number of recent analyses point toward CG and IC flashes being nearly equally energetic (Gallardo and Cooray, 1996; DeCaria et al., 2000; Fehr et al., 2004). The production efficiency of NO_x by lightning is set by constraining the global annual LNO_x to 5 Tg N for the reference year 1998, a number recommended by Lee et al. (1997) and commonly applied in CTM studies. Due to meteorological variations, the net production of NO_x from lightning may be slightly different from 5 Tg N in other years, as the scale factor of the reference year (1998) remains constant. For the year 1997, the total emission by lightning amounts to 5.65 Tg N, of which 91% occurs between 30° S and 30° N. The lightning NO_x is distributed vertically following lightning NO_x profile shapes obtained by Pickering et al. (1998). These profiles are scaled to cloud top heights in TM3 with the following specifications: (1) all IC NO_x and 70% of CG NO_x is placed between T=-15°C and cloud top, (2) 10% of CG NO_x is placed between the Earth's surface and T=-15°C, and (3) 20% of CG NO_x is placed in the boundary layer. Subsequently, the lightning NO_x within a model layer is distributed proportional to the mass of each layer.

4.1.2 H5 scheme

The H5 scheme is based on the observed relation between the lightning activity and approximately the fifth power of the storm cloud height H (Price and Rind, 1992). There is additional observational evidence for the validity of applying a fifth power law to cloud top heights from Ushio et al. (2001), with a reported uncertainty of ± 2 on the power 5 number. In TM3 maximum altitudes of convective transport are used as measure for the storm dimension H . Apart from the spatial

and temporal distribution of the lightning flashes, all other specifications are identical to those in the CP scheme. An important deviation from the “standard” H5 scheme is that the distribution of flashes for marine clouds ($\sim H^{1.73}$) is replaced by the distribution of flashes for continental convective clouds ($\sim H^{4.9}$) scaled with 0.1, a factor that supposedly corrects for weaker convection over sea (Levy et al., 1996). For 1997, the total nitrogen lightning emissions is 6.4 Tg N yr⁻¹, of which 86% between 30° S and 30° N.

4.2 Comparison method

Analysed meteorological fields represent a reconstruction of the actual meteorological state based on observations. The lightning schemes are driven by cloud parameters taken from the ECMWF analyses, which enables TM3 to approximately position the LNO_x production at the actual locations and times of convective activity. Modelled LNO₂ profiles are simulated by taking the difference of two TM3 model runs, one run with the lightning parameterization included, and one run with lightning excluded. LNO₂ profiles are interpolated in time and space to the location of the GOME pixel.

4.2.1 Averaging kernels

In order to compare modelled NO₂ with the GOME tropospheric column observations we compute a modelled GOME-equivalent tropospheric column \hat{x}_{LNO_2} based on the model LNO₂ profile x_{LNO_2} and the averaging kernel A :

$$\hat{x}_{LNO_2} = A \cdot x_{LNO_2}. \quad (2)$$

The advantage of a comparison through the kernel is that the comparison is now independent of the a priori profile shape chosen in the retrieval (Eskes and Boersma, 2003) and that cloud-covered pixels can be compared more realistically. The contributions to the (forward model parameter) error in the comparison now only originate from errors in the slant column and representativeness errors in the altitude-dependent air mass factor (see Boersma et al., 2004).

4.2.2 Masking NO_x source areas

Note that, contrary to the modelled pure lightning NO₂ column, the observed column comprises contributions of LNO₂ but also from contributions by biomass burning, urban, and soil NO_x emissions as well as inflow from the stratosphere. Therefore we apply a masking scheme to exclude areas with known urban and biomass burning emissions. First the highly industrialised Northern Hemisphere is ruled out, leaving the six tropical regions defined in Fig. 10. These regions are subject to additional masking using the DMSP Optical Linescan System (OLS) global nighttime lights climatology (Elvidge et al., 2001) as a proxy for urban NO₂ emissions. Monthly-mean ERS-2 Along-Track Scanning Radiometer (ATSR) fire counts (Arino and Melinotte, 1999) serve as a proxy to exclude areas recently exposed to biomass

Table 2. TM3 grid cell acceptance criteria based on OLS nighttime lights climatology. The relative intensity applies to the average (binned) relative light intensity in a 2.5°×2.5° TM3 grid cell.

Relative intensity	Decision
<4%	Accept grid cell
4–8%	Reject grid cell
8–20%	Reject grid cell and 8 surrounding grid cells (3×3)
>20%	Reject grid cell, 8 surrounding, and 3 adjacent East and West grid cells (3×5)

Table 3. TM3 grid cell acceptance criteria based on monthly ATSR fire counts maps. The relative intensity applies to the summed number of fires in a 2.5°×2.5° TM3 grid cell.

No. of fires in month	Decision
0	Accept grid cell
<50	Reject grid cell and 8 surrounding grid cells (3×3)
50–100	Reject grid cell and 8 surrounding grid cells, and 3 adjacent East and West grid cells (3×5)
>100	Reject grid cell, 8 surrounding, and 2×3 adjacent East and West grid cells (3×7)

**Fig. 6.** GOME observed tropospheric NO₂ as a function of the TM3 modelled LNO₂ (H5) column, for the Australian region defined in Fig. 10. Shown is a 1997 average for scenes with small cloud fractions. Due to the masking of areas exposed to biomass burning the winter-spring period is sampled more often. Error bars correspond to the standard deviation of the mean of the observations in a given bin. The line represents an error-weighted linear fit.

burning. These maps capture the seasonal variability of biomass burning patterns.

Application of the criteria to accept or reject grid cells based on OLS and ATSR data is tabulated in Tables 2 and 3. Masking based on OLS data effectively excludes large areas in South America, South Africa, Perth and vicinity, and Eastern Australia.

In spite of the masking described above, it cannot be ruled out that NO_x produced in urban or biomass burning may still affect the comparison. Boundary-layer NO₂ has a lifetime

of 6–24 h (Beirle et al., 2003), long enough to occasionally cross distances of the order of 100–500 km and flow into our analysis area. This is the main motivation to mask also adjacent grid cells in situations of high fire counts and high relative light intensity. NO₂ that is rapidly transported upward and out of the boundary-layer, for instance by the same deep convective processes that are associated with lightning NO_x production, may live even longer. This potential error source will be discussed in more detail in Sect. 4.3.2.

4.3 Correlation between GOME NO₂ and modelled LNO₂

As an example we present the 1997 annual mean correlation (1997) between GOME observed tropospheric NO₂ and collocated TM3 LNO_x (H5 scheme) for Australia in Fig. 6. Only observations with a cloud reflectance fraction less than 50% have been selected, corresponding to FRESCO cloud fractions smaller than ≈0.15. Modelled and observed columns are stored on the 2.5°×2.5° TM3 grid. Only grid cells with at least three GOME observations were used in the analysis. The good correlation coefficient ($r=0.82$) demonstrates that, on average, observed patterns of NO₂ are in good agreement with simulated LNO₂ patterns over Australia. For all regions we find convincing annual correlations with coefficients ranging from 0.66 to 0.91 (not shown). For CP-simulated LNO₂ we find similar high spatial correlation coefficients (not shown).

4.3.1 Spatial and temporal correlation methods

In the comparisons between modelled and observed NO₂ fields we focus on the spatial and temporal patterns, and not on the average NO₂ amounts (background). Modelled and observed lightning NO₂ columns are generally

$<0.5 \cdot 10^{15}$ molec. cm⁻², and even a small bias in observed NO₂ may lead to considerable errors in an estimate of the ratio between observed and modelled NO₂. This statistical pattern-amplitude comparison method is less sensitive to possible offsets in either modelled or observed columns.

Correlations in space and time between GOME and model are studied independently. The temporal approach compares the time dependence of modelled LNO₂ and observed NO₂ at a given location and consists of a linear least squares regression of modelled LNO₂ and observed total NO₂ for a particular grid cell i . Taking into account all data for 1997 results in slope s_i and intercept o_i for every individual grid cell. The regressions also account for errors on the individual observations. A minimum of at least 5 observations in 1997 is required for a grid cell to be included in the comparison. Subsequently, the 1997 average regional slope is determined as a weighted mean of the individual grid cell slopes:

$$\bar{s}_t = \frac{\sum_{i=1}^n s_i w_i}{\sum_{i=1}^n w_i}, \quad (3)$$

with w_i the inverse of the variance of s_i .

The comparison in temporal variability between TM3 LNO₂ and GOME NO₂ columns is illustrated for a grid cell in the Congo basin. The left panel of Fig. 7 shows a timeseries of TM3 LNO₂ (triangles) and GOME (squares) NO₂ columns at 8.75° S, 18.75° E for observations with cloud reflectance $<50\%$. The period covers January–April 1997 before the start of the biomass burning season in the grid cell. The right panel shows the corresponding correlation and least squares fit of the timeseries with a correlation coefficient of 0.78 and a slope of 2.38 ($n=14$).

In the spatial correlation method, data of one day is compared for a complete region, with the regions defined in Fig. 10. A plot of all pairs of model LNO₂ and GOME NO₂ values results in a slope s_d and intercept o_d for a given day. At least 5 gridcells with observations are required for a day to be included in the analysis. Subsequently a weighted mean for 1997 is computed based on the individual values for s_d :

$$\bar{s}_s = \frac{\sum_{d=1}^n s_d w_d}{\sum_{d=1}^n w_d}, \quad (4)$$

with w_d the inverse of the variance of s_d , and n the number of days for which a slope was computed.

Spatial patterns related to LNO₂ emissions may well resemble NO₂ patterns related to other emissions such as biomass burning. For instance, slopes in NO₂ between land and sea are common to most sources of NO₂ as their origins are concentrated over continents. The temporal correlations, in contrast, are not influenced by such an overlap of emission areas. We expect that temporal patterns for individual sources are more different because lightning, biomass burning and soil NO_x emissions all have their own characteristic temporal behaviour. As a consequence, the spatial and temporal correlation approaches can be seen as largely independent methods to estimate the LNO₂ concentration.

Fig. 7. An example of the temporal correlation method for a TM3 modelled LNO₂ and GOME observed NO₂ column timeseries from 1 January to 1 May 1997, for the model grid cell at 18.75° S, 8.75° E (Congo, Africa).

4.3.2 Correction for other sources

The intercept of regressions like the one shown in Fig. 6 can be interpreted as that part of the NO₂ observation which has a pattern orthogonal to the modelled LNO₂. This background part is attributed mainly to sources other than lightning. The intercept in Fig. 6 ($+0.24 \times 10^{15}$ molec. cm⁻²) is small compared to the range of values found. Similar small intercept values between -0.05 and 0.20×10^{15} molec. cm⁻² are found for other regions. These results show that our masking scheme is efficient in reducing the influence of other sources, enhancing the significance of the regressions.

However, part of the NO₂ distribution resulting from other emissions will not be orthogonal to the LNO₂ distributions. The slopes s of the regressions as shown in Figs. 6 and 7 need to be corrected for contributions from other sources that have similar patterns as LNO₂. This is done by simulating GOME observations with TM3 for the same subset of observations, and computing slopes s_{sim} between these simulated observations of the total NO₂ column and the simulated LNO₂. In other words, we compute again slopes following Eqs. (3) and (4) but now by comparing TM3 total NO₂ to TM3 lightning NO₂. Hence, the slope s_{sim} is representative for the modelled ratio of $\langle x_L + x_O, x_L \rangle / \langle x_L, x_L \rangle$ where $\langle \rangle$ denotes the covariance. This can be written as $1.0 + x_O/x_L$ for the part of x_O that correlates positively with patterns of x_L , with x_L the simulated LNO₂ column and x_O the simulated contributions of other sources to the total NO₂ column. The other sources include soil and biomass burning emissions, as well as inflow of anthropogenic emissions (including aircraft emissions). Subsequently, we account for the influence of other sources by subtracting the slope correction term ($s_{sim} - 1$) from s .

Slope corrections ($s_{sim} - 1$) range from +0.08 to +0.46 for the CP parameterization and from +0.15 to +0.43 for the H5

Table 4. Slope corrections ($s_{sim}-1$) from TM3 LNO₂ vs. TM3 total NO₂ analyses. These numbers were computed with the temporal and spatial correlation method for grid cells with cloud-free observations.

Area	CP		H5	
	Temporal	Spatial	Temporal	Spatial
Pacific Ocean	0.19	0.22	0.33	0.38
South America	0.08	0.08	0.21	0.21
Atlantic Ocean	0.09	0.23	0.23	0.26
Africa	0.13	0.31	0.15	0.20
Indian Ocean	0.36	0.35	0.43	0.41
Australia	0.23	0.46	0.18	0.41

scheme. For cloudy situations we find similar slope corrections. Table 4 summarizes the results of the simulation for both the temporal and spatial methods for both schemes for clear-sky scene situations. Indeed, results from the spatial correlation method are influenced by other sources of NO_x with similar spatial patterns. This is reflected in, on average, slope correction terms that exceed the slope correction terms for the temporal method by +0.07. Intercepts are $(0.02-0.11)\times 10^{15}$ molec. cm⁻², giving an estimate of NO₂ from other sources in TM3 with patterns orthogonal to LNO₂. Generally, slope corrections are smaller than the slopes from the GOME-TM3 comparison themselves, providing confidence in the final results.

One source of NO_x that interferes with LNO_x are soil emissions. In TM3 a time-independent climatology of soil emissions is used, that does not take into account that soil emissions are triggered by precipitation (“pulsing”, Yienger and Levy, 1995). The annual pulsing soil NO_x emission budget is estimated to amount to 1.3 Tg N yr⁻¹ (Yienger and Levy, 1995), compared to approximately 5 Tg N yr⁻¹ from lightning. Because pulses last for several days, only a fraction of the pulsed NO_x will be transported to high altitudes by uplifting in convective systems, and NO_x concentration patterns from soil pulsing will not fully coincide with LNO_x patterns. Moreover, Huntrieser et al. (1998) found that over Europe, with high levels of boundary layer NO_x, still more than 80% of the NO_x in large thunderstorms originated from lightning. We estimate that boundary layer NO₂ columns for summertime Europe are at least 50 times larger than daily columns from soil (0.1×10^{15} molec. cm⁻², Beirle et al. (2004); Jaeglé et al. (2004)), so we expect the systematic effect of “pulsing” on UT NO_x levels to be small.

The uncertainty estimate for the slope correction ($s_{sim}-1$) is based on the combined estimates of soil and biomass burning emission uncertainties. Soil emissions in TM3 are 5.5 Tg N/yr after canopy reduction (Yienger and Levy, 1995) with an uncertainty of 40%. TM3 biomass burning emissions are 6.9 Tg N in 1997, and as a measure of the uncertainty we use a number obtained from Duncan et al. (2003) who re-

port an interannual variability in biomass burning emissions of approximately 10%. Error estimates for the slope corrections have been obtained by applying a 10% increase and decrease in biomass burning and 40% increase and decrease in soil emissions. From these runs, we arrive at uncertainties in $s_{sim}-1$ of 0.02–0.15.

4.4 Mean regional slopes

Results of statistical regressions can be misleading and are easily overinterpreted. This is a main motivation to investigate as many independent estimates as possible. The spread in values found then provides an independent error estimate and is a check for the robustness of conclusions drawn. Independent analyses have been performed for:

- The subset of cloud-free and cloudy observations.
- The temporal and spatial correlation methods.
- The CP and H5 parameterization schemes.
- The various tropical regions.

Regional mean slopes and intercepts corrected for the influence of non-lightning NO_x sources are presented in Fig. 8. The upper panel of the figure shows the results for the CP scheme, and the lower panel for the H5 scheme for both the spatial and temporal method in situations of clear-sky GOME observations. Over the tropical continents mean slopes for the CP scheme are 0.9 for Africa and 1.4 for Australia, clearly higher than over South America (0.6). For the H5 scheme mean slopes over tropical continents are all close to 1.0 for both the spatial and temporal method, indicating a remarkable agreement in modelled LNO₂ and observed NO₂. Over tropical oceans both the H5 and CP scheme significantly overestimate LNO₂ concentrations. The error bars on the slopes have been computed as the combined uncertainty on $s_{s,t}$ and s_{sim} . Here we express the error variance of the mean regional slopes by adding contributions from the estimated error in the regression coefficient and from the estimated error in the slope correction term, i.e. $\langle \epsilon^2 \rangle = \sigma_{s,t}^2 + \sigma_{sim}^2$.

There is a number of model lightning parameterization aspects that may explain the regional differences in slopes:

- CP (specific). The CP scheme assumes a constant rainfall to lightning flash ratio. However, there are several papers reporting on strong regional differences in rainfall-to-lightning flash ratios between different continents (e.g. McCollum et al., 2000), and between continents and oceans (e.g. Petersen and Rutledge, 1998; Allen and Pickering, 2002).
- Both schemes assume that the energy ratio of CG and IC flashes equals 10. However, Gallardo and Cooray (1996) suggested that this ratio is more likely to have a value of approximately 1.0. DeCaria et al. (2000) and

Fehr et al. (2004) both suggest that the ratio is closer to 1.0 than to 10. As the (occurrence) fraction of IC lightning flashes of total lightning is higher over continents than over oceans (e.g. Kurz and Grewe, 2002), a CG:IC energy ratio of approximately 1.0 would effectively increase slopes over the oceans at the cost of slightly smaller slope values over the continents at constant initial LNO_x emissions.

- Both schemes also assume that convective intensity is 10 times stronger over continents than over ocean. Strong overestimations in parameterized marine lightning flash ratios have been found for the H5-scheme by Jourdain and Hauglustaine (2001) who assumed a similar (5 times) convective intensity ratio. Increasing the continent divided by ocean convective intensity ratio would effectively reduce the overestimation in LNO₂ produced over oceans, due to the scaling to a fixed global annual LNO_x production.

With respect to this last issue, it is interesting to note that the observed continent divided by ocean LNO₂ production ratio presented in Sect. 3 has a value of only 1.6 at 10:30 h local time, apparently in contrast with a value exceeding 10 required here. However, convective activity over land is at a distinct minimum at 10:30 h local time, and the continent:ocean ratio is expected to be much higher in the afternoon. For instance, TRMM data (Ushio et al., 2001) could be used to investigate the diurnal cycle of continent divided by ocean lightning activity.

As discussed in Sect. 3, cloudy observations are sensitive to errors in the vertical distribution of NO₂. Nevertheless, they constitute an independent data sample and we may interpret the results from the cloudy analysis as independent from the clear-sky results. The NO_x originating from mostly yesterday's lightning will largely reside above (today's) cloud cover, where GOME has a large sensitivity compared to clear-sky. Boundary layer pollution, on the other hand, will be effectively shielded from view by the presence of clouds and near-ground contributions to the NO₂ column will influence the comparison differently. The study for cloudy grid cells shows similar results for most regions except for South America and the Indian Ocean (Fig. 9).

For the CP scheme, considerable differences are found over South America. Cloudy-sky situations give a slope that is 0.4 smaller than for clear sky. Over the Indian Ocean the spatial correlation method gives a slope that is 0.5 larger for cloudy than for clear-sky situations, opposed to an insignificant difference for the temporal method. For the H5 scheme, cloudy-sky slopes are 0.6 smaller than clear-sky slopes. Over the Indian Ocean the spatial method gives a slope that is 0.5 higher than the slope from the temporal method, just as in the CP analysis.

The higher slopes for clear observations over South America may be related to the fact that cloud-covered

Fig. 8. Mean (corrected) slopes and intercepts of the GOME tropospheric NO₂ columns as a function of TM3 LNO₂, for the six regions shown in Fig. 10. GOME observations with small cloud reflectance fractions (<0.5) and modelled LNO₂ columns based on the CP lightning scheme (top panel) and H5 scheme (lower panel) are used. Dark grey: slopes for the temporal regression; light grey: slopes for the spatial regression; black: mean intercepts expressed as fraction of the absolute mean (temporal method). Error bars combine uncertainties of the mean regional slopes and the bias correction.

observations have mainly been taken in the rainy season and cloud-free observations mainly during the rest of the year. For all regions apart from South America, the average difference between clear and cloud covered observed columns is $+0.01 \times 10^{15}$ molec. cm⁻². South America, however, shows clear-sky columns that are on average $+0.15 \times 10^{15}$ molec. cm⁻² larger than cloudy-sky observations. As correlation coefficients for the clear ($r=0.77$) and cloudy-sky ($r=0.69$) situations are similar, this may indicate that the cloud covered data sample over South America is

Fig. 9. As Fig. 8, but now for GOME observations with cloud reflectance fractions >0.5 .

likely to represent a different lightning regime. Cloud cover is highest over South America in the DJF and SON seasons, and these seasons appear to have less LNO_x production than modelled in the MAM and JJA seasons.

The difference between cloud covered results for the temporal and spatial methods over the Indian Ocean may well reflect the enhanced sensitivity of the spatial method for similar spatial patterns from other NO_x sources. Plumes of tropospheric NO₂ originating from Africa and Indonesia can develop during the monsoon transition periods over the Indian Ocean as described by Kunhikrishnan et al. (2004). These plumes are associated with enhanced mid-tropospheric NO₂ concentrations originating from mainly biomass burning in Africa and Indonesia. Especially in so-called monsoon transition periods such as April–May, and September–October, NO_x from continental surface sources is transported to the MT and UT by deep convection. The continental MT and UT

NO_x subsequently follow the same transport pathways as UT LNO_x, resulting in a similar spatial distribution of biomass burning NO_x and LNO_x over the Indian Ocean. These similar patterns may well explain the enhanced spatial slope relative to the temporal slope. The temporal method is designed to track variations with time at one given location and hence additional NO_x increases from other sources are more likely to result in higher intercepts than in higher slope values. Indeed, the temporal scheme features intercepts over the Indian Ocean higher by +0.30 (CP), +0.43 (H5) compared to the spatial method. The fact that there is no significant difference between the two methods for clear-sky situations may therefore be related to the fact that the cloud-free observations do not sample the monsoon (i.e. clouded) transition period.

5 Tropical LNO₂ maps

Figure 10 shows the modelled LNO₂ for the CP and H5 schemes and the GOME observations for 1997, corrected for estimated contributions of other sources of NO_x. This contribution is taken as $x_O = (s_{sim} - 1.0) \cdot x_L + o$ with $s_{sim} - 1.0$ the slope correction from Table 4, x_L the modelled LNO₂ column, and o the intercept. It is important to note that the maps of Fig. 10 represent the annual mean LNO₂ distribution for clear-sky situations. Note that slopes as discussed above cannot be directly inferred from these plots, since these are determined from modulations (in space and time) on top of the average patterns in Fig. 10. The purpose of these maps is mainly to visually compare average modelled and “observed” LNO₂ patterns.

The TM3 simulations and measurements are shown for clear-sky situations only in 1997. Over the large ocean regions where no masking is applied and many clear-sky observations are available, the fields represent a yearly average. Over continents, the fields should not be regarded as annual means, as grid cells may have been sampled during one season or for a few occasions only due to masking or few available cloud-free observations.

Both TM3 and GOME NO₂ in Fig. 10 show enhanced values over the tropical continents. Also the “outflow” patterns off the South American West coast and – in the CP scheme – for the Eastern Atlantic seem to agree reasonably. But there are also distinct differences: TM3 shows higher lightning NO₂ values than GOME over most of the oceans, consistent with the low slope values in Fig. 8. Furthermore it shows that the GOME fields exhibit much stronger spatial variability than TM3. This may be related to observational noise and the incomplete removal of contributions of other NO₂ sources affecting the comparison.

6 Global LNO_x production in 1997

In Sect. 4 we have shown that observed GOME NO₂ values correlate well with model predicted patterns of NO_x

Fig. 10. Average (1997) lightning NO₂ column as modelled with the CP scheme (top panel), modelled with the H5 scheme (middle panel), and observed by GOME (bottom panel) as a function on longitude and latitude. Columns in 10¹⁵ molec. cm⁻².

produced by lightning. The Southern Hemisphere tropical regions used in our study contain a considerable fraction of the total global LNO_x source, namely about 35–50%. Therefore we can use the GOME/model slopes to derive a top-down estimate of the global LNO_x production.

6.1 Approach

The ratio between observed and modelled atmospheric quantities of LNO₂, is given by regional slopes s_j with j the index number for a region ($j=1$ for the Pacific Ocean, $j=2$ for South America and so on). Hence, the annual LNO_x

Table 5. Results from 8 methods to estimate the global LNO_x production. The column headed “World” includes the random error estimate. The column headed “Total error” combines the random and systematic contributions to the error estimate.

Scheme	Method	Observation type	World	Total error	40° S–5° N
CP	Temporal	Clear sky	3.2±0.8	1.4	1.1±0.2
CP	Spatial	Clear sky	2.7±0.7	1.2	1.0±0.2
CP	Temporal	Cloudy sky	2.3±0.9	1.2	0.9±0.2
CP	Spatial	Cloudy sky	2.8±0.8	1.3	1.3±0.2
H5	Temporal	Clear sky	4.6±0.8	1.8	1.0±0.1
H5	Spatial	Clear sky	4.5±0.8	1.8	1.1±0.1
H5	Temporal	Cloudy sky	3.9±1.5	2.0	1.0±0.1
H5	Spatial	Cloudy sky	4.0±1.2	1.8	1.4±0.1
Average:			3.5±0.9	1.6	1.1

production P_G is estimated by rescaling the modelled production P_T as follows:

$$P_G = P_T \frac{\sum_j s_j \bar{x}_j a_j}{\sum_{j=1}^n \bar{x}_j a_j}, \quad (5)$$

with x_j the mean simulated LNO₂ column, and a_j the total surface of area j .

6.2 LNO_x production in the 40° S–5° N area

Application of Eq. (5) with $j=1,\dots,6$ allows for a direct rescaling of the modelled production P_T over the 40° S–5° N area. The slopes s_1 to s_6 are directly deduced from Figs. 8 and 9. We assume that the annual average net transport of LNO₂ into the 40° S–5° N area is negligible. Note that LNO_x transport between the regions 1 to 6 is considerable, making it difficult to estimate the production per region. Furthermore we also assume that chemistry can be approximated to be linear in the TM3 difference run.

For the CP scheme, 2.7 Tg N is produced in the 40° S–5° N area. This production is rescaled directly with the slopes presented in Fig. 8. Using slopes from the temporal correlation method for clear-sky observations, this approach rescales the modelled 2.7 Tg N LNO_x production to 1.1 Tg N. For the H5 scheme, 2.2 Tg N is produced in the 40° S–5° N area and this is rescaled with the slopes obtained with the temporal correlation method for clear-sky situations to 1.0 Tg N. This number is very close to the rescaled value of 1.1 Tg N obtained for the CP-scheme, even though the original CP and H5 LNO_x production differed by (2.7–2.2=) 0.5 Tg N.

6.3 Global LNO_x production

An estimate of the annual global LNO_x production P_G requires important assumptions on the observation/model slopes outside the 40° S–5° N area. We arrive at an estimate from Eq. (5) for $j=1,\dots,10$, where s_7 (continent) and s_8 (ocean) are the estimated slopes for the 5° N–30° N area, and s_9 (continent) and s_{10} (ocean) the same for the rest of the

world. The basic assumption is that we may use the mean continental and ocean slopes derived from the 40° S–5° N area for $s_7 - s_{10}$.

In the CP scheme, more than 50% of the LNO_x production takes place outside 40° S–5° N, and these emissions can only be rescaled indirectly. For these areas we assume for oceans $s_7, s_9=0.93$ and for continents $s_8, s_{10}=0.21$, corresponding to the mean continent and ocean slopes determined in the 40° S–5° N regions for the CP scheme. The values for x_j and s_j outside the tropical areas have been derived from the same model runs as used to determine the slopes within the analysis area. Using s_7 and s_8 in 5° N–30° N, we find that the LNO_x production there is rescaled from 2.5 to 1.7 Tg N in 1997. Outside of the tropics, LNO_x production is rescaled through s_9, s_{10} from 0.5 to 0.4, a relatively small reduction as the relative area of continents is larger than in the Southern Hemisphere. In effect, the global LNO_x production is rescaled from 5.7 to 3.2 Tg N.

In the H5 scheme, more than 60% of the LNO_x production takes place outside 40° S–5° N. Using $s_7, s_9=0.19$ and $s_8, s_{10}=1.03$, we find a LNO_x reduction outside 40° S–5° N from 4.2 Tg N to 3.6 Tg N. Thus, the global LNO_x budget for 1997 for the H5 scheme is rescaled from a model value of 6.4 to (1.0+3.6=) 4.6 Tg N. The difference with the 3.2 Tg N derived for the CP-scheme is largely due to extrapolation assumptions, as the rescaled values within the 40° S–5° N area are only 0.1 Tg N apart.

In this work 8 methods, of which 4 are independent, to determine slopes s_j have been applied. Table 5 summarizes the estimates for the global LNO_x production based on the results from the 8 experiments. The arithmetic mean of the 8 experiments is 3.5 Tg N, and individual results range from 2.3–4.6 Tg N. The H5 results are on average systematically higher by about 1.5 Tg N than the CP results. This is mainly a consequence of the determination of the budget outside the 40° S–5° N analysis area as all methods give very similar results within the analysis area.

6.3.1 Random errors

The errors in s_j are estimated from combining the errors associated with the statistical comparison and the errors in the slope correction term. The uncertainty in s_j is thus determined by GOME observation errors, model pattern errors (i.e. meteorology) and by errors in the modelled strength of other NO_x sources.

Random errors in P_G have been determined from errors in the individual slopes s_j . As explained above, the slopes of the individual regressions contain uncertainties that account for both the spread of points around the straight line fit, and GOME retrieval errors. Subsequently the uncertainty-weighted mean of these individual regressions for region j is determined (e.g. averaging over grid cells for the temporal method). In the 40° S–5° N area, these correspond to the uncertainties reported in Figs. 8 and 9. These slope errors are typically between 0.1 and 0.2. In the 5° N–30° N area, we assume that the standard deviation from the mean (ocean, continent) derived for regions 1 to 6 is a reasonable estimate for the uncertainty in s_7 and s_8 since this area is still characterised as “tropical”. These uncertainties are on average 0.3. For the extratropical slopes s_9 and s_{10} , we conservatively estimate the uncertainty to be 1.0. A measure of the random error in the overall global production P_G can be determined with two methods:

- The random error (or standard deviation) in a single estimate of the global LNO_x production can be obtained if we assume that errors in the slopes are uncorrelated. The error variance $\langle \epsilon_{P_G}^2 \rangle$ is calculated from the error propagation of uncertainties in the regional slopes s_j (with n_j the number of grid cells used per area j) as:

$$\begin{aligned} \sigma_{P_G}^2 &= \langle \epsilon_{P_G}^2 \rangle \\ &= \sum_{j=1}^{10} \left(\frac{P_T \cdot \bar{x}_j \cdot n_j}{\sum_{j=1}^{10} \bar{x}_j \cdot n_j} \right)^2 \sigma_{s_j}^2. \end{aligned} \quad (6)$$

The uncertainties σ_{P_G} for the 8 estimates are in the 0.7–1.5 Tg N range with an average value of 1.0 Tg N. Table 5 quotes the individual uncertainty estimates in P_G . The random error for the estimate of the LNO_x production within the 40° S–5° N area is on the order of 10%–20% only.

- We can use the spread in values of the 8 experiments as estimate of the error on the mean. The data set presented in Table 5 has a standard deviation of 0.9 Tg N.

These two independent ways of estimating the random error produce a very similar result. The value for the statistical error seems to indicate that we have obtained a rather precise estimate of the LNO_x production. Taking the arithmetic mean we arrive at 3.5 ± 0.9 Tg N.

6.3.2 Systematic errors

One approach in estimating the systematic error in P_G (B_{P_G}) is to assume that the errors in the slopes s_j are correlated. In such an approach, errors in the GOME observations and in the GOME-model comparison are interpreted as biases. A first order estimate of the deviation from the true value for P_G may then be obtained as follows:

$$B_{P_G} = \sum_{j=1}^{10} \left(\frac{P_T \bar{x}_j n_j}{\sum_{j=1}^{10} \bar{x}_j n_j} \right) \sigma_{s_j}. \quad (7)$$

For B_{P_G} we find values between 1.0 Tg N (CP, clear sky, spatial method) and 2.3 Tg N (H5, cloudy sky, temporal method) with an average of $B_{P_G} = 1.4$ Tg N.

Apart from this approach, there may be important systematic errors related to (1) the GOME observations, to (2) the model, and to (3) the regressions. Each of these types of errors is discussed below.

6.3.3 GOME errors

Not all systematic errors in GOME observations introduce errors in the slopes in Table 5. If the observed columns suffer from a constant bias, this will result in an increase (decrease) of the offset o_j , and not translate in a systematically erroneous s_j value. Only if a bias scales with the reported column value, s_j will be in error. Thus, as GOME columns are inversely proportional to the air mass factor, systematic overestimations in the AMF are expected to lead to underestimated slopes. However, most of the LNO₂ is deposited in the upper troposphere where GOME has a high sensitivity and AMF errors are generally small. Systematic AMF errors are to be identified and eliminated, which is beyond the scope of this paper.

There may also be difficulties in accurately observing patterns of NO₂ because there may be stratospheric patterns which are not modelled well in the assimilation part of the retrieval approach. However, since the results in Table 5 for cloud-free and cloud-covered scenes are consistent, this strengthens our confidence in the GOME retrievals and both AMF and assimilation errors are likely small.

6.3.4 TM3 errors

In our method to rescale modelled regional LNO_x productions, we need to be especially suspicious of the model’s capability to accurately reproduce spatial and temporal patterns of LNO₂. Systematic model errors are not easy to quantify, and we have chosen a practical approach to assess the possible impact on our production estimates. The following gives an overview of possible systematic model errors:

- Incorrect NO_x lifetime.
- Errors in the vertical distribution of LNO_x production.

- Errors in photo-chemistry.
- Errors in parameterization of convection and cloud top heights.

A reasonably well described lifetime in TM3 is essential to estimate the production of LNO_x from modelled and observed concentrations of NO₂. An incorrect NO_x lifetime would result in too high or low overall concentrations if transport is described realistically. This would in turn lead to systematic errors in the slopes. The literature however provides support that TM3 produces realistic NO_x distributions. For instance, we note that various studies (Emmonds et al., 1997; Wauben et al., 1997; Meijer et al., 2000) have indicated that TM3 is capable of reproducing aircraft- and surface-observed NO_x concentrations for a range of different meteorological and chemical situations. Also, recent studies by Brunner et al. (2003, 2005) showed that TM3 is well capable of reproducing observed NO_x and NO_x-related species.

The vertical distribution of LNO_x influences the horizontal distribution and observed spatial patterns. We expect that the effect of errors in the vertical distribution of LNO_x is small. For instance, both Kurz and Grewe (2002) and Jourdain and Hauglustaine (2001), using similar parameterizations to the CP and H5 schemes, respectively, found large flash density overestimations over oceans. Therefore we argue that the overestimations of oceanic LNO₂ that we find are a result of flash density overestimation rather than the result of errors in the modelled vertical distribution of lightning NO_x. Moreover, a recently submitted paper by Labrador et al. (2004b) shows little difference in LNO_x concentrations for model runs with the vertical LNO_x distribution according to Pickering et al. (1998) and a vertical distribution in the 5 highest layers of the convective cloud. The same is found by Oliv   (2005) who used a lightning parameterization based on convective updrafts.

The relation between LNO_x production and the NO₂ concentration in the atmosphere is in reality non-linear. This is consequence of the photochemical production of ozone via NO_x, leading to OH-formation. This radical may – depending on chemical and meteorological conditions – constitute an important sink for NO_x. The scaling of the LNO_x budget based on the slopes observed neglects this non-linearity. This may be an issue especially for the oceans where the slopes found are significantly smaller than one. The partitioning of nitrogen between NO₂ and NO, and between NO_x and NO_y is also a potential source of model error. Even if the lifetime of NO_x and NO_y is modelled correctly, errors in the NO₂:NO ratio, for instance due to errors in the modelled ozone concentration, would result in incorrect slopes. Fortunately, Brunner et al. (2005) show that a comparison of TM3 modelled ozone and in situ measurements of ozone over the South Pacific gives quite reasonable agreement, indicating that slope errors due to ozone errors over the South Pacific are likely small.

The description of clouds in numerical weather prediction analyses is known to be problematic, especially in the tropical regions. The modelled LNO_x is sensitive to a correct timing and strength of convective complexes. The representation of these processes on the model grid of 2.5 degree resolution causes additional errors. Nevertheless, we found on average good correlations between modelled LNO₂ and observed NO₂ columns, indicating that the major features of NO₂ distribution resulting from modelled convection-related emissions and subsequent transport are realistic.

6.3.5 Comparison errors

Apart from errors directly related to the TM model and to GOME, there are also errors that may result from our statistical analysis, indirectly related to GOME and model errors. Therefore, we set up a simple study to provide a qualitative estimate of errors that may occur in the comparison of patterns in independent data sets. The upper panels of Figs. 11 and 12 show fictitious modelled (solid line) and observed (dashed line) patterns. The observations are based on assumed “true” patterns (shown as dotted line) with added random observational noise. Subsequently, the pattern was simulated with a model that suffers from two types of systematic errors. These errors are either a (spatial or temporal) mismatch with the “true” pattern (a shift, Fig. 11), or an exaggerated (spatial or temporal) smearing or diffusion of the “true” pattern (Fig. 12).

The spatial correlation method is sensitive to errors in the spatial distribution of LNO₂ patterns. Relevant systematic errors are to be expected in the modelling of the transport, lifetime and vertical distribution of LNO₂. The shift experiment also has an interpretation for the temporal method, as LNO_x production may take place too early or too late in the parameterizations, leading to a shifted temporal pattern

Processes such as deep convection typically take place on a scale much smaller than the size of a grid cell. For instance, in the H5 scheme ECMWF cloud heights are sampled once every 6 h, giving instantaneous values, clearly too low to properly resolve much shorter periods of thunderstorm and lightning activity. The model may thus suffer from errors in representing such processes. Furthermore, numerical diffusion in the advection, vertical transport processes and the limited resolution of the model tend to smoothen NO₂ structures. Part of this effect is taken care of by averaging the GOME observations over model grid cells before making the comparisons. To simulate this effect we also study the correlation of the “true” toy pattern with a smoothed (smeared) version.

The lower panels of Figs. 11 and 12 show the result of our systematic error study. One important requirement in this study is that the correlation coefficients between “observed” and “modelled” patterns do not fall below ~0.65, the lowest regional value found in our 1997 average correlation of GOME and TM3 columns.

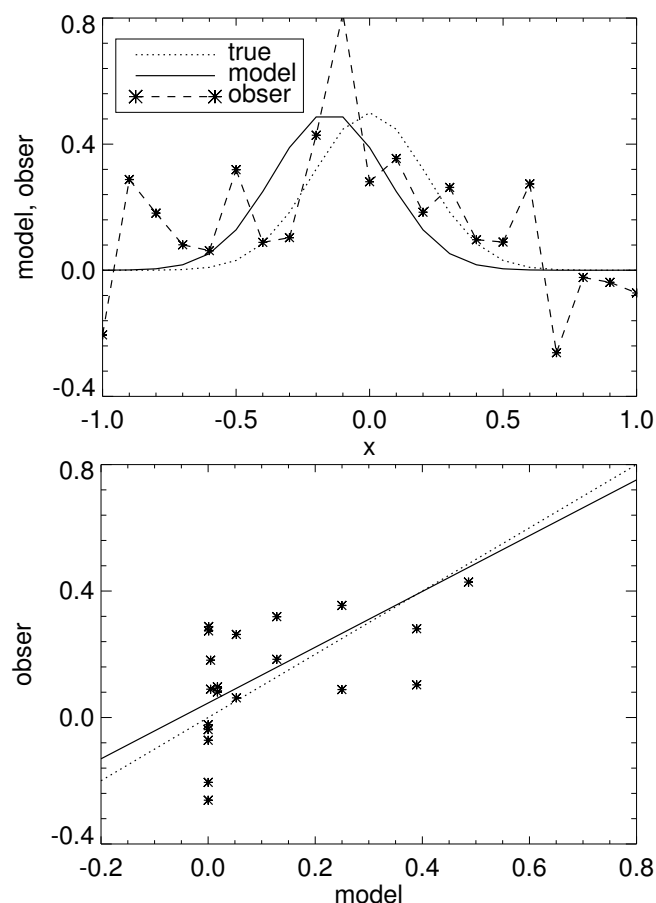

Fig. 11. Shift experiment. Upper panel: simulated observed and modelled patterns against arbitrary x-axis units (distance, time). Lower panel: corresponding regression analysis of observation vs. model (solid line). The dotted line indicates the regression line if there was no systematic error in the model and no noise on the observations.

The upper panel of Fig. 11 shows a model pattern shifted by -50% relative to the width (0.3 x-axis units) of the “true” pattern. The observed pattern follows the “true” pattern but has an additional random error that is typical for gridded GOME observations. The lower panel shows the regression plot corresponding to the data presented in the upper panel: the solid line gives the least squares regression fit ($s=0.88\pm 0.26$), and the dashed line gives the $y=x$ line ($s=1.00$) that we expect if the model and observations would agree. The correlation coefficient $r=0.66$ for this example. By repeating this experiment with random noise 1000 times we arrive at, on average, a systematic slope underestimation $\Delta g=-0.20$ (± 0.13) and $\Delta o=+0.05$ for a mean correlation coefficient $r=0.70$. Apparently, a (spatial or temporal) shift of half a unit (i.e. half a grid cell, half a time step) results in underestimations of the slope of approximately 20%.

Fig. 12. Smearing experiment. Same as in Fig. 11, but now for a “smeared” pattern.

We conducted a similar experiment with a model pattern smeared by 50% (width now 0.45 x-axis units) relative to the “true” width of the pattern. No shift was assumed and the random errors are similar to the previous experiment. The lower panel of Fig. 12 shows a regression fit with a $s=1.44$ (± 0.37) for an $r=0.65$. Repeating this experiment 1000 times we arrive at a significant systematic slope error of $\Delta g=+0.35$ (± 0.18) and $\Delta o=-0.10$ for a mean correlation coefficient $r=0.83$. In conclusion, if the model smears “true” patterns systematically by 50%, slopes may be overestimated by up to 35%. Note that a smearing factor of 50% is on the high side and that possible systematic “smearing” errors such as diffusion, or representativity of instantaneous cloud heights, are likely less than 50%.

Generally, a strong shift in a modelled pattern results in a loss of correlation between model and observation. In such situations, a model-observation scatter shows a strong scatter of points. A strong smear effect in TM3 is expected to result in a strong, non-linear shape of the distribution of points in a model-observation comparison. Since neither of these are observed in Fig. 6 nor in any of the annual average

correlation figures for the other continents (not shown), it seems that neither shift nor smearing errors in TM3 have systematically influenced the results in Table 5. This also follows from our simple experiment: shifts and smears up to 60% are still consistent with correlations found in the GOME-model comparison (minimum $r=0.65$). The errors from the shift and smearing experiments are (−20%,+35%) and from these numbers we conservatively estimate the systematic error to amount to an additional error of (±)35% in the estimated global LNO_x production budget. As the signs of these effects are opposite, we expect at least a partial cancellation of errors from shift and smear effects.

6.3.6 Total error estimate

Model shifts and smears are just two examples of possible systematic errors. Nevertheless, their effects may lead to systematic errors with opposite signs. CTM-experiments typically suffer from a variety of possible systematic errors, and therefore an ensemble of systematic errors is sometimes treated as a random error. Subsequently we proceed by combining all the errors as though they were random and independent:

$$\sigma_{\text{final}}^2 = \langle \epsilon_{\text{random}}^2 \rangle + \langle \epsilon_{\text{syst}}^2 \rangle. \quad (8)$$

We calculate total errors for the 8 individual estimates of the LNO_x production budget given in Table 5 by using Eq. (8). The systematic error (ϵ_{syst}) is assumed to be 0.35. Results are summarised in Table 5 in the column headed “Total error”.

In summary, the results of the 8 experiments range from 2.3–4.6 Tg N, largely due to systematic errors associated with extrapolation of the slopes to areas of the globe not covered by our analysis. A more conservative view consists of taking the largest and smallest P_G values from the 8 readings and adding resp. subtracting the estimated standard error in P_G . This leads to an estimated LNO_x production in the 1.1–6.4 Tg N range.

7 Conclusions and outlook

Nitrogen dioxide measurements of GOME are sensitive to NO₂ produced by lightning. In situations with high clouds, the tropospheric NO₂ column shows a rapid increase consistent with the parameterization of Price and Rind (1992). The observed increase can be well described with an empirical power-law, where the LNO_x increases with the cloud top height as $H^{4.9 \pm 2}$. The uncertainty in the observed value of the power is estimated to be 40% related to assumptions with respect to background NO₂ concentrations. We interpret this relationship as strong evidence that GOME is capable of detecting LNO_x production. From the ratio of the increases found over continents and oceans, we estimate that continental storms are stronger by a factor of 1.6 in producing LNO_x at the 10:30 h local time of observation.

Modelled LNO₂ and observed tropospheric NO₂ patterns are found to correlate surprisingly well, with spatial correlation coefficients $r \approx 0.80$ in 1997 in six distinct tropical regions between 40° S and 5° N. We use spatial and temporal correlations to determine linear regression coefficients for these 6 tropical regions. The intercepts of these regressions show that these regions are little affected by NO_x emissions from other sources. The slopes, corrected for possible influences of other NO_x sources, indicate that TM3 significantly overestimates LNO_x emissions over the oceans. Over tropical continents, we find a good quantitative agreement between modelled LNO₂ and observed NO₂. This is true for two different lightning parameterizations, one based on convective precipitation, and one based on the fifth power of the cloud top height. The modelled overestimations over oceans may be reduced if the assumed energy ratio (10:1) between cloud-to-ground and intra-cloud lightning is decreased. An increase in the assumed ratio (10:1) between continent-to-ocean convective intensity is also expected to reduce modelled oceanic LNO_x overestimations. This work also suggests that for the convective precipitation scheme, there are significant regional differences in rainfall-to-lightning ratios that should be accounted for.

By rescaling the original LNO_x production modelled by TM3 for the year 1997, 8 estimates of the global LNO_x production have been obtained. We find that the LNO_x production between 40° S and 5° N amounts consistently to $\sim 1.0 \pm 0.2$ Tg N for both the CP and H5 schemes. Here the error bar accounts for random errors only. Assuming that the slopes may be extrapolated to the rest of the world, we arrive at a global LNO_x production of approximately 2.8 Tg N yr^{-1} for the CP and 4.3 Tg N for the H5 model version. The difference between these two estimates is largely due to assumptions with respect to extrapolating slopes to the rest of the world. Random errors in these estimates are dominated by errors in the observations and in the correction of the slopes for the influence of other sources. Accounting for random errors the LNO_x production is estimated as $3.5 \pm 0.9 \text{ Tg N}$ in 1997. Accounting for random and systematic errors, as well as the range of independent estimates, LNO_x production is conservatively estimated in the 1.1–6.4 Tg N range.

This study presents a first attempt to estimate the global LNO_x production by comparing observed NO₂ with modelled LNO₂ distributions. Such estimates can be extended by repeating this method for all years between 1996 and 2004, covered by the GOME and SCIAMACHY measurements, as well as future NO₂ observations provided by OMI and GOME-2. Especially NO₂ and cloud observations from OMI are expected to contribute to improved estimates of LNO_x: the small OMI pixels of $13 \times 24 \text{ km}^2$ are better suited to resolve convective complexes. Also, the OMI 13:30 h local time overpass time is closer to the maximum in the diurnal cycle of convective activity over continents.

Future work should investigate the effect of reduced CG:IC energy ratio's and increased convective intensity

ratio's on the capability of models to reproduce observed LNO₂ patterns. Recently, TM3 has been extended with an updraft velocity-based lightning scheme that has shown promising results in the literature (Allen and Pickering, 2002; Kurz and Grewe, 2002; Oliv   et al., 2005²). LNO₂ patterns modelled with this scheme are to be compared to satellite data. Moreover, a proper description of convective activity in chemistry-transport models remains crucial for accurate parameterizations of lightning activity. Convective mass fluxes are not always stored in operational meteorological data and in such situations simplified schemes are used for diagnosis. More advanced schemes for the diagnosis of convective mass fluxes in chemistry transport models are clearly needed. Also, the temporal and spatial scale of lightning activity is much smaller than most model resolutions. Hence, increasing the model resolution is expected to improve the description of convection and convection-related processes such as lightning.

Acknowledgements. The authors acknowledge S. Beirle and T. Wagner (IUP-Heidelberg) for providing the GOME DOAS NO₂ slant columns and for stimulating discussions. M. van Weele and P. van Velthoven are acknowledged for advice on the TM3 model and comments.
