3.3 Sampling and analysis

A detailed description of the WAD/SJAC and the analytical procedures is given elsewhere (Slanina et al., 2001; Wyers et al., 1993). A simplified sketch of the sampling system is shown in Fig. 2. The air flow through the instrument (∼171 min⁻¹, STP) was generated by a scroll pump outside the wooden house and could be adjusted with a needle valve. The flow was measured continuously (1 min time resolution) with a mass flow meter (Bronkhorst, F-112AC-HA-55-V). After the sample air passed the steel elbow and/or pre-impactor and the PFA Teflon tubing, it entered a horizontally aligned WAD that scavenges soluble gaseous species. Trace gases (such as NH₃, HNO₃, HNO₂, HCl and SO₂) were collected in a 10⁻⁴ M NaHCO₃ absorption solution. The liquid input was controlled automatically by an infrared sensor and a switching valve and the liquid was continuously pumped out of the denuder at a flow rate of 0.5–0.6 ml min⁻¹ by a peristaltic pump. The liquid effluent was collected in a sample reservoir (“gas sample”, see Fig. 2). Artifacts due to evaporation of aerosol phase species in the WAD can be excluded because the characteristic time for formation/evaporation of NH₄NO₃ is >10 s (Dlugi, 1993), while the mean residence time of the sample air in the WAD is ∼0.002 s (annulus volume: 0.0018 l, flow rate: ∼171 min⁻¹).

After the WAD, the air entered a reservoir where it was mixed with steam of highly purified water. The supersaturation causes aerosol particles to grow rapidly (within 0.1 s) into droplets of at least 2 µm diameter. These droplets, containing the dissolved aerosol species were then collected in a cyclone (Khlystov et al., 1995). The cyclone effluent (“aerosol sample”) was transferred into the sample reservoir by a peristaltic pump at a flow rate of 0.5–0.6 ml min⁻¹.

Collection of liquid samples in the sample reservoir and the following analytical cycles were performed successively for gas and aerosol sample. On-line analyses were carried out using a mobile IC with suppressed conductivity detection. The system was operated with an HPLC separation column ( Dionex, IonPac AS12A, 4 mm) preceded by a guard column ( Dionex, IonPac AG12A, 4×50 mm). Samples were injected via a 199 µl loop into 2.7 mM Na₂CO₃–0.3 mM NaHCO₃ eluent. Internal Br⁻ standard addition using a peristaltic pump was performed continuously to calibrate the IC. The conductivity cell of the IC was temperature-stabilized at 30°C and therefore conductivity measurements were independent from room temperature.

Ammonium (NH₄⁺) was determined by FIA (Wyers et al., 1993). The general principle is the addition of OH⁻ ions, converting NH₄⁺ to NH₃, which will then pass through a Teflon membrane and is taken up by highly purified water. Subsequent NH₃ detection is based on conductometry. The conductivity cell of the FIA was not temperature controlled; therefore, conductivity measurements were dependent on temperature. Despite operating an air conditioner, diel temperature variations from 22°C at night to 30°C at daytime were observed in the laboratory. Fluctuations of the conductivity due to temperature changes in the air conditioned laboratory were corrected using:

\[ \text{Condcorr} = \text{Cond} \times e^{(0.024 \times (20-T))} \]  

(4)

where Condcorr denotes the corrected conductivity value (mV), Cond is the original measured conductivity (mV) and T is the observed temperature (°C) in the laboratory. The FIA was calibrated once every week using standard solutions of 50 ppb and 250 ppb NH₄⁺.

IC and FIA analyses were performed simultaneously for each sample. The analytical sample cycle was purged with ambient air after every run to avoid memory effects of the previous sample solution. The sampling system is fully automated and its software controls the sequence of sample
Table 2. Standard deviations \( \sigma_x \) contributing to the total measurement uncertainty \( \sigma_m \). (index \( x \) is the mixing ratio of the compounds found in aerosol or gas sample \( m_{liq} \), the mixing ratio of the \( Br^- \) standard solution \( m_{Br(std)} \), the liquid flow through the system \( Q_{liq} \), the analyzed \( Br^- \) mixing ratio \( m_{Br} \) or the air mass flow through the system \( Q_{air} \)).

Ambient mixing ratios for gas and aerosol species after IC analyses were determined using the following equation:

\[
m = \frac{m_{liq} \times m_{Br(std)} \times Q_{liq} \times G \times M_{air}}{m_{Br} \times Q_{air} \times M_i} \tag{5}
\]

where \( m \) is the ambient mixing ratio (ppb), \( m_{liq} \) is the mixing ratio of the compounds found in aerosol or gas sample (ppb), \( m_{Br(std)} \) is the mixing ratio of the \( Br^- \) standard solution (ppb), \( Q_{liq} \) is the liquid flow through the system (sum of sample and \( Br^- \) standard flow) (kg s\(^{-1}\)), \( G \) is the factor to convert the molar weight of ionic compounds analyzed into the molecular weight of the corresponding trace gas (the factor is 1 for aerosol species), \( M_{air} \) is the molar mass of air (28.96 kg kmol\(^{-1}\)), \( m_{Br} \) is the analyzed \( Br^- \) mixing ratio (ppb), \( Q_{air} \) is the air mass flow through the system (kg s\(^{-1}\)), and \( M_i \) is the molar weight of compound \( i \) (kg kmol\(^{-1}\)). This equation is also valid for calculating ambient mixing ratios of \( NH_3 \) and aerosol \( NH_4^+ \), excluding the addition of the \( Br^- \) standard solution to the sample flow.

4 Results and discussion

The sampling period was chosen from 12 September to 14 November 2002, covering extensive biomass burning activity during the dry season (12 to 23 September), an intermediate phase (transition period, 7 to 31 October) and clean conditions during the wet season (1 to 14 November). Due to an instrument failure no samples were collected from 24 September to 7 October.

All results of our measurements of gas and aerosol species are presented as mixing ratios (ppb). All quantities were calculated for standard conditions of 298.15 K, 1000 hPa and dry air, following the recommendations from Schwartz and Warneck (1995) and Mills et al. (1993).

4.1 Estimation of measurement uncertainty

The uncertainty of the measurements was estimated applying “Gaussian Error Propagation” to the relationship (5) which resulted in the following formula:

\[
\sigma_m = \sqrt{\left( \frac{\sigma_{m_{liq}}}{m_{liq}} \right)^2 + \left( \frac{\sigma_{m_{Br(std)}}}{m_{Br(std)}} \right)^2 + \left( \frac{\sigma_{Q_{liq}}}{Q_{liq}} \right)^2 + \left( \frac{\sigma_{m_{Br}}}{m_{Br}} \right)^2 + \left( \frac{\sigma_{Q_{air}}}{Q_{air}} \right)^2}
\tag{6}
\]

where \( \sigma_m \) is the estimated relative uncertainty of the ambient mixing ratio (ppb) and \( \sigma_x \) are the standard deviations of the corresponding parameters (see Eq. 5). Equation (6) was also used to estimate uncertainties for ambient mixing ratios of \( NH_3 \) and aerosol \( NH_4^+ \), excluding the error associated with the addition of the \( Br^- \) standard solution to the liquid sample.
flow. Calculated total uncertainties $\sigma_m$ for all measurements and compounds usually ranged from 10–15%, indicating a reliable and stable performance of the instrument. The standard deviations $\sigma_x$ contributing to the total measurement uncertainty $\sigma_m$ including their sources are listed in Table 2. For IC analyses, the contribution of $\sigma_{Q_{\text{liq}}}$ was highest (57% of the total error, see Table 2) indicating that the application of peristaltic pumps for the transport of liquid solutions (Br$^-\text{standard and/or sample}$) is the largest source of measurement error. For FIA analyses, the value of $\sigma_{\text{mliq}}$ had the highest contribution to $\sigma_m$ (84% and 57% for NH$_3$ and NH$_4^+$ analyses, respectively). Reasons for that may be an incomplete removal of the temperature dependence by Eq. (4), and also the temperature influence on the equilibrium constant of NH$_4$OH and the permeation of NH$_3$ through the membrane.
