Abstract. A lightning NO\textsubscript{x} (LiNOx) source has been implemented in the deep convection scheme of the Meso-NH mesoscale model following a mass-flux formalism coherent with the transport and scavenging of gases inside the convective scheme. In this approach the vertical transport of NO inside clouds is calculated by the parameterization of deep convective transport, thus eliminating the need for a-priori LiNOx profiles. Once produced inside the convective column, NO molecules are redistributed by updrafts and downdrafts and detrained in the environment when the conditions are favorable. The model was applied to three particular flights during the Tropical Convection, Cirrus and Nitrogen Oxides (TROCCINOX) campaign over the tropical area around Bauru on 3-4 March 2004. The convective activity during the three flights was investigated using brightness temperature at 10.7 \mu m observed from GOES-12 satellite. The use of a model-to-satellite approach reveals that the simulation appears rather realistic compared to the observations. The diurnal cycle of the simulated brightness temperature, CAPE, number of IC flashes, NO entrainment flux are in phase, with a succession of three marked peaks at 18:00 UTC (15:00 LT). These simulated peaks precede the observed afternoon one by about three hours. Comparison of the simulated NO\textsubscript{x} with observations along the flight tracks show that the model reproduces well the observed NO\textsubscript{x} levels when the LiNOx source is applied. The budget of entrainment, detrainment and LiNOx convective fluxes shows that the majority of the NO detrained back to the environment comes from lightning source inside the convective columns. Entrainment of NO from the environment and vertical transport from the boundary layer were not significant during the episode. The troposphere is impacted by detrainment fluxes of LiNOx from 4 km altitude to 16 km with maximum values around 14 km altitude. Detrainment fluxes vary between 75 kg(N)/s during nighttime to 400 kg(N)/s at the times of maximum convective activity. Extrapolation of the regional LiNOx source would yield a global LiNOx production around 5.7 Tg(N/year which is within the current estimates but should not hide the overestimation of the number of flash rates by the model.

1 Introduction

Ozone is produced in the troposphere by photochemical oxidation of hydrocarbons and CO catalysed by hydrogen oxide radicals (HO\textsubscript{a} = OH + HO\textsubscript{2}) and nitrogen oxide radicals (NO\textsubscript{a} = NO + NO\textsubscript{2}). Consequently changes in atmospheric NO\textsubscript{x} concentrations can lead to a modification in the rate of ozone production. NO\textsubscript{x} is emitted into the atmosphere from various natural and anthropogenic sources, including fossil fuel combustion, biomass burning, aircraft emission and lightning (Brasseur et al., 1996; Bradshaw et al., 2000). Evidences of NO\textsubscript{x} production by lightning were given by airborne measurements in and near mature thunderstorms. Observations at different latitudes show that NO\textsubscript{x} can be increased considerably (as much as a few ppbv) in the upper troposphere on small spatial scales (Huntrieser et al., 1998; Dye et al., 2000; Huntrieser et al., 2002; Skamarock et al., 2003)

It is still poorly known how much NO\textsubscript{x} is produced by the storms and how this production relates to cloud parameters like particle phase, updraft strength, cloud top height, or flash rate, which all would be useful for parameterisations of NO\textsubscript{x}-production. Consequently, estimates of the global NO\textsubscript{x} production by lightning in thunderstorms still differ by about one order of magnitude, between 1–20 Tg(N)/year (Price et al., 1997; Lee et al., 1997; Huntrieser et al., 1998). This uncertainty can have great implications in terms of NO\textsubscript{x} budget, especially in the southern hemisphere where the LiNOx source dominates in the upper troposphere (Lamarque et al.,...
1997; Zhang et al., 2000; Martin et al., 2000; Hauglustaine et al., 2001).

Although the convective clouds and lightning are local processes, the impact of the LiNOx source is global. The typical lifetime of NOx increases from a few hours in the planetary boundary layer to a few days in the upper troposphere, where it can take part in the formation of HNO3, HNO4 and PAN. While PAN can act as a NOx reservoir, HNO3 can efficiently be scavenged. LiNOx is closely linked with OH radical production and hence can impact on the oxidizing capacity of the troposphere (Labrador et al., 2004). The chemistry within the high NOx plume originated from lightning, their long-range transport and their potential importance in sustaining background NOx far from source regions is still a challenge for global and regional model (Crawford et al., 2000; Tie et al., 2001; Brunner et al., 2003; DeCaria et al., 2005).

Recent satellite observations have demonstrated that, on the global scale, lightning activity is highest over tropical continental areas (Christian et al., 2003). The Tropical Convection, Cirrus and Nitrogen Oxides (TROCCINOX) experiment took place over southern Brazil and provided the first measurements of LiNOx near deep convective clouds over a continental region in the tropics. This paper focuses on particular convective episodes of the TROCCINOX 2004 experiment when LiNOx production was found in the upper troposphere. The objective is to quantify the amounts of LiNOx produced in well-characterised cloud formations and scale up the results of the mission to provide regional estimates of lightning NOx.

2 Model description

The model used in this study is the Meso-NH model. A full description of the model capabilities is available on http://www.aero.obs-mip.fr/mesonh (Lafore et al., 1998). One single domain is used with a horizontal grid of 100×100 points at 30 km resolution and 70 levels with grid spacings from 40 m (bottom) up to 600 m (top). The altitude of the model top is at 27 km. The time step is 30 s. The model starts on 2 March at 00:00 UTC and runs for 66 h. The physics of the model includes the prognostic calculation of the turbulence and a convection scheme based on mass-flux calculations (Bechtold et al., 2001). A mixed-phase microphysics and the subgrid cloudiness are available for these simulations. The surface fluxes are provided by the ISBA (Interaction among Soil-Biosphere-Atmosphere) model (Noilhan, 1989) for the natural patches and TEB (Town Energy Balance) model (Masson et al., 2000) for the urbanized patches. The radiation scheme is the ECMWF scheme (Mlawer et al., 1997). The chemistry scheme includes 37 chemical species representative of the O3-NOx-VOC chemistry (Crassier et al., 2000). Emissions are from the EDGAR 3.2 1995 database (Olivier et al., 2001a, b). The initial and large-scale mixing ratios for chemistry and the meteorological initial and boundary conditions are provided by the MOCAGE (MOdèle de Chimie Atmosphérique de Grande Echelle) model (Josse et al., 2004; Massart et al., 2005).

The deep convection scheme of Meso-NH (Kain and Fritsch, 1990; Bechtold et al., 2001) has been already adapted by Mari et al. (2000) for the transport and the scavenging of soluble gases.

The mass flux formalism applied to the convective transport of a chemical compound $C$, writes:

$$\frac{\partial C}{\partial t}_{\text{convection}} = -\frac{1}{\rho A} \frac{\partial (MC)}{\partial z} - \overline{w} \frac{\partial C}{\partial z} \quad (1)$$

where $A$ is the grid mesh area, $\rho$ is the air density, $M$ is the mass flux (in kg/s) and $\overline{w}$ is the environmental subsidence to compensate the upward mass flux. $C$ is the mixing ratio of chemical compound in the convective cells. The mass flux term of Eq. (1) is further decomposed into:

$$\frac{\partial (MC)}{\partial z} = \frac{\partial (MuC^u)}{\partial z} + \frac{\partial (MdC^d)}{\partial z} \quad (2)$$

where the superscripts $u$ and $d$ refer to the “updrafts” and to the “downdrafts” components, respectively. The different mass flux divergences are expressed as:

$$\frac{\partial}{\partial z} (MuC^u) = \epsilon^u C - \delta^u C^u \quad (3)$$

$$\frac{\partial}{\partial z} (MdC^d) = \epsilon^d C - \delta^d C^d \quad (4)$$

where $\epsilon$ and $\delta$ are the parameterized entrainment and detrainment rates, respectively. Selecting $C$ as the mixing ratio of nitrogen monoxide, [NO], Eqs. (3–4) are modified to include the internal LiNOx production rates:

$$\frac{\partial}{\partial z} (Mu[NO]^u) = \epsilon^u [NO] - \delta^u [NO]^u + (\overline{vA}) \frac{\partial [NO]^u}{\partial t}_{\text{LiNOx}} \quad (5)$$

$$\frac{\partial}{\partial z} (Md[NO]^d) = \epsilon^d [NO] - \delta^d [NO]^d \quad (6)$$

The two terms on the right hand side of Eqs. (5 and 6) represent the subgrid scale transport of NO. Transport of NO is assumed to take place instantaneously during each model timestep. The third term is the LiNOx term to be parameterized. For this simulation, no lightning production is allowed in the downdrafts. It is worth noting that no a-priori vertical placement of LiNOx is necessary with this approach. Once produced inside the convective column, NO molecules are redistributed by upward and downward transport and detrained in the environment. The vertical placement of LiNOx is a direct consequence of the redistribution by mass fluxes inside the convective scheme. This approach is different to what has been done in several global and regional models in which the vertical placement of LiNOx was prescribed (Jourdain et al.,...
2001; Meijer et al., 2001; Grewe et al., 2001; Labrador et al. 2004; Park et al., 2004; Labrador et al., 2005) based on cloud-scale modelling studies (Pickering et al. 1998).

The electrical activity in the thunderstorms is related to the vertical extent of the glaciated region where ice-ice particle rebounding collisions are efficient enough to explain the charging mechanisms (Reynolds et al., 1957; Takahashi, 1978; Saunders, 1992). A growing electrical field then results from the organization of dipolar, tripolar or even more complex charge structures at storm scale (Rust and MacGorman, 2002; Rust and Marshall, 1996; Stolzenburg, 2002; Barthe et al., 2005). The electrical field is broken down by a partial neutralization of the electrical charges. This is realized by a repetitive triggering of intra-cloud (IC) and cloud-to-ground (CG) flashes. The flashes lead to the formation of NO in the lightning channels after dissociation of air molecules at high temperature followed by a rapid cooling. According to the statistical regression formula of Price and Rind (1992), the total lightning frequency over land, \( f_f \) can be grossly estimated from mean cloud morphological parameters:

\[
f_f = 3.44 \times 10^{-5} H_{ct}^{1.9}
\]

(7)

\( H_{ct} \) is the cloud top height of the convective cells (in km).

Price and Rind (1993) proposed the following polynomial relationship between the thickness of the cold icy cloud (\( H_{fr} \) in km) and the IC/CG ratio, \( \beta \):

\[
\beta = 0.021 H_{fr}^3 - 0.648 H_{fr}^2 + 7.493 H_{fr} + 36.54 H_{fr} + 63.09
\]

(8)

with \( 1 < \beta < 50 \).

A scaling factor \( c_{pr} = 0.97241 \times \exp(0.048203 \times \Delta \text{lat} \Delta \text{lon}) \) is introduced by Price and Rind (1994) to adapt \( f_f \) to different mesh sizes in interval of latitude (\( \Delta \text{lat} \)) and longitude (\( \Delta \text{lon} \)) given in degree.

The combination of Eqs. (7–8), leads to the final expression of the \( \text{LiNO}_x \) production rates to be inserted in Eq. (5). It can be written in condensed form:

\[
\frac{\partial (\text{NO})^u}{\partial t} \bigg|_{\text{LiNO}_x} = \frac{\beta f_f}{1 + \beta} \times P(\text{IC}) + \frac{f_f}{1 + \beta} \times P(\text{CG})
\]

(9)

where the value of the mean production rate per CG and IC namely, \( P(\text{CG}) = 6.7 \times 10^{26} \) of NO molecules, and \( P(\text{IC}) = 6.7 \times 10^{25} \) of NO molecules, of Price et al. (1997) have been retained. It is worth noting that recent studies based on airborne observations and cloud scale modeling found that intracloud flashes are likely to be as effective in producing NO as cloud-to-ground flashes (DeCaria et al., 2000; Zhang et al., 2003; Fehr et al., 2004; Ridley et al., 2005). It is also important to note that the estimates for the lightning NO\(_x\) production based on Price and Rind (1992, 1994) and Price et al. (1997) are on the high end of current estimates in the literature (Labrador et al., 2005).

It is important to note that although the NO\(_x\) source vertical distribution is not specified a-priori, it is implicitly controlled by the vertical distribution of lightning flashes in the model. The practical implementation of the \( \text{LiNO}_x \) parameterization is based on critical vertical levels defined in the deep convection scheme. IC flashes are equally distributed between the cloud top and the freezing levels. The CGs are located between the \(-10^\circ\text{C}\) level (or the level of free sink if below) and the ground. The NO production in flashes is assumed to be proportional to air density following Goldbaum and Dickerson (1993). Recent studies have shown that unimodal or bimodal distributions would be more realistic than uniform distributions as discussed in MacGorman and Rust (1998) and DeCaria et al. (2000, 2005). The sensitivity of \( \text{LiNO}_x \) sources to these assumptions during TROCCINOX is not covered by the present work. A 1D version of the model was run for one episode during the TOGA-COARE experiment in order to test the sensitivity of the NO\(_x\) to the vertical placement of CG and IC. The comparison shows that the altitudes of maximum \( \text{NO}_x \) in upper troposphere for were very close in the uniform and multimodal cases. The only notable difference was around the level of \(-15^\circ\text{C}\) isotherm where the multimodal approach gives a local maximum. Although the parameterized convective scheme treats the entrainment and detrainment fluxes, the first order effect is to bring the \( \text{LiNO}_x \) up to the cloud outflow region with low sensitivity to the altitude of the source inside the convective column.

3 Experiment and meteorological situation

3.1 Experimental design

The instrumented campaign took place in February-March 2004. The investigated region was the tropical area around Bauru (22°19' S, 49°07' E) in the São Paulo state of Brazil (Fig. 1). The region is located within the zone of most intense South Atlantic convergence zone (SACZ) convection (Liebmann et al., 1999; Carvalho et al., 2004). During the austral summer, it is characterized by frequent and vigorous mesoscale convective systems sometimes associated with extreme precipitation events (Nougès-Paegle and Mo, 1997; Liebmann et al., 2001; Carvalho et al., 2002; Carvalho et al., 2004). Most thunderstorms are associated with cold front convection in a mountainous terrain, although local thunderstorms and mesoscale convective systems are also present. In the region further west of the Bauru area, the thunderstorm characteristics are associated with local conditions, fronts, and the proximity of the Bolivian high (Pinto and Pinto, 2003). The southeastern Brazil is also one of the principal region in terms of lightning activity (Pinto et al., 1996, 1999a, b) with flash densities higher than 10 flashes km\(^{-2}\) year\(^{-1}\) (Pinto and Pinto, 2003; Pinto et al., 2003).

A fully instrumented research high flying aircraft (ceiling altitude of about 12 km), a Falcon 20, operated in the middle and upper troposphere. During the intense measurement campaign the aircraft operation was coordinated with
Fig. 1. Simulated meteorology on 3 March at 12:00 UTC (09:00 LT): (a) mean sea level pressure in hPa and wind vectors at the surface, (b) wet-bulb potential temperature in K and wind vectors at 850 hPa. The inside domain is used for Figs. 3, 4 and 5.

Fig. 2. Same as Fig. 1 on 4 March at 18:00 UTC (15:00 LT).
detailed ground-based and space borne systems (Schumann et al., overview paper in preparation). Observations in the boundary layer were also available from the Brazilian low-level aircraft although not during the dates studied here. This study focuses on three particular flights operated by the German Falcon 20 on 3–4 March. These flights were dedicated to the study of lightning NOx with observations of both fresh and aged LiNOx emissions. Flight 09 was a morning flight from 10:00 UTC to 14:05 UTC (07:00 LT to 11:05 LT) designed to sample the background environmental conditions, before the impact of the afternoon convective activity. Flight 10 took place in the afternoon of the same day during the peak of convective activity. The aircraft operated close to the Bauru radars and sampled outflow of fresh LiNOx emissions. Flight 11 was devoted to the study of more aged airmasses with the objective to understand how the convection from the day before impacts the ozone budget over the region.

3.2 Mesoscale situation on 3–4 March

The SACZ is a northwest-southeast oriented quasi-stationary region of enhanced convection that extends southeastward from the ITCZ region anchored over the Amazon region into the South Atlantic Ocean. Each individual SACZ episode is composed of one or several midlatitude cold fronts that intrude into the subtropics and tropics, becoming stationary for a few days over southeastern Brazil (Carvalho et al., 2004; Liebmann et al., 1999). Figs. 1b and 2b show the southern branch of the SACZ extending partially over the southern South Atlantic. The SACZ is characterized by high values of wet-bulb potential temperature ($\theta_w$) at 850 hPa, representative of moist and warm air masses. The position of the associated cold front is determined by the line of strong $\theta_w$ gradient along a North-West South-East axis. At 850 hPa, dry and cold air masses are simulated behind the cold front with low $\theta_w$ values (<320 K). Between 3 March and 4 March at 18:00 UTC (15:00 LT), the high pressure system moves from the continent toward the south Atlantic, pushed north-eastward by the cold front (Fig. 1). In the free troposphere, on 3 March at 12:00 UTC (09:00 LT), the Bauru area remains under the influence of northwesterly flow with continental origin. While the front moves northeastward over the ocean on 4 March, the flow turns more southeasterly but the Bauru region remains under the influence of warm and humid airmasses. North of the cold front, the simulated upper troposphere has relatively low ozone mixing ratios, ranging from 50–60 ppbv (not show) in agreement with the observed ozone mixing ratios. On contrast, the region south of the cold front is strongly impacted by the subtropical jet stream and the subsidence below the front. In the upper and mid-troposphere, higher ozone mixing ratios (>80 ppbv) are found in the model, most probably of stratospheric origin and large-scale advection associated with the jet.

3.3 Convective activity

The convective activity that occurred during the three Falcon flights is now documented using brightness temperatures (BT) at 10.7 $\mu$m observed from GOES-12 satellite at 12:00 and 21:00 UTC 3 March and 18:00 UTC 4 March (Figs. 3, 4 and 5). In addition, the synthetic BTs calculated from the simulation are also shown. Indeed, the use of the so-called model-to-satellite approach allows us a direct comparison between simulated BT with those observed from satellite (e.g., Morcrette, 1991; Chaboureau et al., 2000; Chaboureau and Bechtold, 2005). The synthetic BT are computed using the Radiative Transfer for Tiros Operational Vertical Sounder (RTTOV) version 8.2 (Saunders et al., 2005). Observed and simulated BTs are displayed on the 30-km horizontal model grid over a sub-domain of 50×50 gridpoints covering the full flight tracks.

At 12:00 UTC 3 March a deep convective cell is observed to the northwest of Bauru (point A in Fig. 3), but is missed by the simulation. Otherwise, not much convective activity...
and LiNOx production are found along the track of the flight 09 in the two images showing a rather good agreement between the observation and the simulation. At 21:00 UTC 3 March, convection is well-developed over all the land part of the domain in both the observation and the simulation (Fig. 4). The convective activity is clearly associated with enhanced NO convective tendencies. The thunderstorm documented during flight 10 presents characteristics of a deep convective event with BTs less than 210 K. Lightning was also observed at 16:57 UTC by the Lightning Imaging Sensor (LIS) on board the Tropical Rainfall Measuring Mission (TRMM). The general organization of the deep convective event is well-captured by the model. However, the simulated event is located a bit too far east compared to the observation. As expected, a perfect match is not attained which makes a point-to-point comparison along the track of flight 10 difficult. At 18:00 UTC 4 March, the observed convective activity and associated NO source have moved further north (Fig. 5). The simulated BTs display a similar pattern, but with lower BTs to the west than the observed ones. The track of flight 11 encounters several convective cells in both the observation and the simulation, but not exactly at the same locations. Overall, the simulation appears rather realistic compared to the observation, but it can miss some individual cells probed by the Falcon. This result is further shown by the time evolution of several variables over the same domain of 50×50 gridpoints (Fig. 6). The average simulated BT displays a comparable time evolution to the observed one, but with less variation from day-to-day. However, the other simulated fields present a succession of three marked diurnal cycles. The average convective available potential energy (CAPE), the total number of intracloud lightning, and the percentage of cloud tops higher than 8 km within the domain are in phase, peaking at 18:00 UTC (15:00 LT). These simulated peaks precede the observed afternoon one by about three hours, as already noted by several studies on the diurnal cycle (e.g., Chaboureau and Bechtold, 2005, among many others).

4 Aircraft observations and model analysis

Flight 09 was designed to study the environmental conditions before the peak of convective activity. The model reproduces well the meteorological parameters (not shown) along the
flight track. Fig. 7 shows the simulated and observed O$_3$ and NO-NO$_y$ mixing ratios along the flight track. Two simulations were performed with and without the lightning source of NO$_x$. Adding the LiNOx source significantly improves the simulation of NO and NO$_y$ with higher mixing ratios at the levels of the Falcon flight (around 12 km) in agreement with the observations. The lightning emission of NO$_x$ is thus the major source of NO$_x$ and NO$_y$ in this region. The impact of the LiNOx source on ozone in the upper troposphere becomes significant during the second half of the flight with an increase of ozone mixing ratio by 10–15 ppbv when the LiNOx source is triggered. During flight 09, the first maximum of NO$_x$ mixing ratio observed by the aircraft during its ascent is well captured. According to the model and satellite images (see previous section), this maximum of NO$_x$ originates from convection southwest of segment A-B in Fig. 3. These high NO$_x$ mixing ratios were then advected thus corresponding to sources of aged lightning NO$_x$. High mixing ratios are again observed and simulated while the aircraft was over the Sao Paolo region, before the final descent toward Gaviao Peixoto, close to Bauru. According to the model results and the satellite images there was no convective activity over the Sao Paolo area at this time (segment G-H-I in Fig. 3). A fast vertical transport of polluted air masses from the megacity is thus unlikely. Indeed, a vertical cross-sections of NO (not shown) shows that the NO uplifted or produced by lightning in the continental convection west of the domain is transported toward the Sao Paolo region and the ocean where it mixes with clean oceanic air.

The second flight (Flight 10) was dedicated to the study of the local convection in the afternoon of the same day. The aircraft remained close to the Bauru radars and sampled fresh LiNOx emissions. Observed NO mixing ratios reached very high values (>15 ppbv). In Fig. 8, although the model
reproduces the two maxima of convection activity at the beginning and the end of the flight, it cannot capture the very high mixing ratios of NO and NO\textsubscript{y} observed during these two periods. The reason for this underestimation is the coarse model resolution compared to the typical spatial and duration scales of the LiNO\textsubscript{x} events. As for flight 09, the ozone mixing ratios are increased by 10 to 20 ppbv at 12 km when the LiNO\textsubscript{x} source is active.

Flight 11 took place the day after and extended the exploration area in the upper troposphere northward up to 12° S. Observed NO and NO\textsubscript{y} mixing ratios were lower than during the previous two flights with NO mixing ratios always less than 2 ppbv (Fig. 9). During this flight, the model tends to overestimate the observed NO and NO\textsubscript{y} mixing ratios. This overestimation of NO\textsubscript{x} by the model can be due to (1) overestimation of convective activity and the associated LiNO\textsubscript{x} source or (2) missing heterogeneous sinks for nitrogen reservoirs like HNO\textsubscript{3}. The formation of HNO\textsubscript{3} occurs through the direct reaction of NO\textsubscript{2} and OH. The destruction rate of HNO\textsubscript{3}, however, is relatively slow with a lifetime of approximately 20 to 30 days in the tropics. Because the photochemical rate of destruction of HNO\textsubscript{3} is much slower than its production rate, especially in the tropics, the cycling of NO\textsubscript{x} through the chemical destruction of HNO\textsubscript{3} is slow (Brasseur et al., 1998). Since the conversion of HNO\textsubscript{3} to NO\textsubscript{2} is slow, the supposed overestimation of HNO\textsubscript{3} in the upper troposphere will not produce a large increase in the NO\textsubscript{x} concentrations. The less efficient conversion of NO\textsubscript{x} to HNO\textsubscript{3} in the upper troposphere allows the increase of NO\textsubscript{x} due to lightning as has been shown by the satellite data (Zhang et al., 2000). Thus NO\textsubscript{x} levels in the upper troposphere will be more strongly impacted by the convective activity than by recycling from HNO\textsubscript{3}. As shown previously, the northern part of the domain was characterized by numerous convective cells, leading to an increase of lightning produced NO\textsubscript{x}. The overestimation of NO\textsubscript{x} by the model is certainly due mostly to the vigorous convective activity simulated during flight 11 together with a memory effect of the upper troposphere to convective activity during the previous 2 days.

5 Regional lightning NO\textsubscript{x} budget

One important aspect of the LiNO\textsubscript{x} budget is to characterize the vertical distribution of the LiNO\textsubscript{x} source and subsequent transport by the updraft and downdraft in the convective
cells. In this paper, the vertical distribution of NO$_x$ is not given a-priori but is a consequence of the diagnosed location of IC and CG flashes, entrainment of environmental air and detrainment at different levels of the clouds (see Sect. 2). The detrainment flux represents what is really gained by the troposphere. Figure 10 shows the total regional convective fluxes, in kg(N)/s/m, calculated from the model over the whole domain of simulation. Entrainment of NO into the convective cells is very low during the three days of simulation. It is interesting to note that the production of NO inside the convective cells is significant from 4 km to 16 km altitude with maxima obtained in the 5 km to 8 km altitude range. Within this layer, the maxima of NO production by lightning increases with time. Detrainment of NO to the environment starts at 4 km altitude and peaks at 12 km on 3 March at 12:00 UTC and 14–15 km during the maximum of convective activity. The maximum of NO detrained to the environment is obtained during the day of maximum regional LiNO$_x$ production on 4 March at 18:00 UTC. From these profiles, it is clear that the NO detrained back to the environment originates from lightning source inside the convective column. Only a small fraction is pumped from the boundary layer. The production of LiNO$_x$ in kg(N)/s/m shows high values below the cloud base which are associated with the production in the CG flashes below the cloud base and to a much lesser extent to the redistribution by downdrafts of LiNO$_x$ produced in the updrafts (no production of LiNO$_x$ is allowed in the downdrafts). There were no appropriate measurements during the studied flights to show whether or not production of NO occured below the cloud base. This production, however, remains confined below the cloud base with very low re-entrainment into the cloud. If the regional vertical profiles of detrainment fluxes of NO are now integrated over the vertical (i.e. sum over the layer from 4 to 16 km height), the total NO production by lightning released to the troposphere ranges between 75 kg(N)/s to 400 kg(N)/s (Fig. 11). The integrated detrainment fluxes have a well pronounced diurnal cycle with peaks between 15:00 and 18:00 UTC like other convective parameters (Fig. 6). The detachment by the downdrafts is two orders of magnitude lower than the detachment by the updrafts (in the layer from 4 to 16 km height). The count of active convective columns in the model varies from 500 (during nighttime) to 3000 (during daytime on 4 March 2004 at 18:00 UTC) which represents about 5 to 30 % of the total number of grid points in the model. This count is coherent with the percentage of observed and simulated deep convective events over the domain (Fig. 6 (middle)). The detachment flux of NO per convective column based on the regional flux divided by the total number of active convective cells gives a production between 0.02 to 0.8 kg(N)/s/convective cell. This production per convective column is in the range of
Fig. 9. Same as Fig. 7 for flight 11.

Fig. 10. Total simulated vertical profiles of convective detrainment flux (solid line), entrainment fluxes (dashed line) and lightning NO production flux (dotted line), in kg(N)/s/m at (a) 12:00 UTC (09:00 LT) on 3 March, (b) 21:00 UTC (18:00 LT) on 3 March 2004 and (c) 18:00 UTC (15:00 LT) on 4 March 2004. The fluxes are summed over the whole domain of the simulation (see Fig. 1).
the production rates deduced from NO\textsubscript{x} storm budgets. During the STERAO campaign, Skamarock et al. (2003) derived a production of about 0.2 kg(N)/s from the observations. A production of 0.058 kg(N)/s/anvil can be deduced from the study of Huntrieser et al. (1998) based on the flux of detrained air in the anvil and aircraft observation of NO\textsubscript{x} mixing ratios in the anvil.

An important objective when studying particular convective episodes is to quantify the contribution of the convection and associated LiNO\textsubscript{x} source to the regional and global nitrogen budget. The extrapolation method, however, is not straightforward. From Christian et al. (2003), a rough estimate of the relative lightning activity occurring over southern America can be derived. From the annual cycle of the global flash rate, it can be estimated that lightning activity in March represents about 8\% of the annual global activity (Fig. 7a of the cited paper). The total number of IC flashes, resp. CG flashes, over the simulated domain during the 66 h period is $2 \times 10^7$, resp. $4 \times 10^6$. The average total number of flashes (IC+CG) is equal to 101 fl/s (respectively 84 fl/s for IC and 17 fl/s for CG) which is higher than the average global annual flash rate 44 fl/s. Such high flash rates have never been reported in the literature and the model certainly overestimates these rates. This could be partly due to the overestimation of the convective activity during the third day of the simulation or to the high sensitivity of flash rates to biases in the cloud top heights (Allen et al., 2000). No ground-based measurements were available for this region and these particular days to quantify the variability of the flash rates during the chosen episode. It is also worth noting that these particular days were not typical average days as they were chosen for their high convective activity. An average LiNO\textsubscript{x} production of $3.4 \times 10^7$ kg(N)/day can be calculated for the domain from the simulated flash rates and the NO\textsubscript{x} production per flash. Following the hypothesis rated above, based on the global to regional ratio of flash rates, a gross extrapolation gives a global LiNO\textsubscript{x} production rate around 5.7 Tg(N)/year. The estimation is well within the range of current estimates (Price et al., 1997; Lee et al., 1997; Huntrieser et al., 1998). This result should not hide the uncertainties on the number of flash rates simulated by the model. This estimate is below the global production rate calculated by Skamarock et al. (2003).
when multiplying the LiNOx production rate in the 10 July STERAO storm by the storm frequency number following Huntrieser et al. (1998). Uncertainties in the LiNOx source are related to the vertical placement of the IC and CG flashes, the number of flashes and NO molecules produced per flash, the initial and lateral boundary NOx profiles and transport parameterization. This work represents a first attempt to deduce a global scale LiNOx budget from a regional scale simulation. To reduce the uncertainties, the parameterized approach has to be compared with explicit electrical schemes at cloud scale (Zhang et al., 2003; Barthe et al., 2006). Further work is needed to reconcile the different approaches and provide a proper way to extrapolate storm and regional NOx budgets to global scale.

6 Conclusions

A lightning NOx source has been implemented in the deep convection scheme of the Meso-NH mesoscale model. The LiNOx scheme is written following a mass-flux formalism coherent with the transport and scavenging of gases inside the convective scheme. No a-priori vertical placement of LiNOx is necessary with this approach. Once produced inside the convective column, NO molecules are redistributed by updrafts and downdrafts and detrained in the environment when the conditions are favorable. The model was applied to three particular flights during the TROCCINOX campaign over the tropical area around Bauru on 3–4 March 2004. These flights were dedicated to the study of lightning NOx with observations of both fresh and aged LiNOx emissions. The convective activity during the three flights was investigated using brightness temperatures at 10.7 µm observed from the GOES-12 satellite. The use of a model-to-satellite approach reveals that the simulation appears rather realistic compared to the observations. The model can miss some individual cells sampled by the aircraft due to the low horizontal resolution of the model compared to the scale of the cells. The diurnal cycle of the simulated brightness temperature, CAPE, number of IC lightning, NO entrainment flux are in phase, with a succession of three marked peaks at 18:00 UTC (15:00 LT). These simulated peaks precede the observed afternoon one by about three hours, as already noted by several studies on diurnal cycle. The comparison of the simulated NOx with observations along the flight tracks show that the model reproduces well the observed NOx levels when the LiNOx source is applied. Exceptions are the very high levels of NOx observed in the anvils during flight 10 and which horizontal and temporal scales can not be resolved by the model. The model tends to overestimate the NOx levels in the upper troposphere during the last flight which could be due to high convective activity in the model. The budget of entrainment, detrainment and LiNOx convective fluxes shows that the majority of the NO detrained to the environment comes from the lightning source inside the convective columns. Entrainment of NO from the environment and vertical transport from the boundary layer were not significant during the episode. The troposphere is impacted by detrainment fluxes of LiNOx from 4 km altitude to 16 km with maximum values around 14 km altitude. Detrainment fluxes vary between 75 kg(N)/s during nighttime to 400 kg(N)/s at the times of maximum convective activity. A first gross extrapolation of the regional LiNOx source gives global LiNOx production around 5.7 Tg(N)/year which is within the current estimates. The model however tends to overestimate the number of flash in light of global mean flash rates. Further work is still needed to reconcile the global, regional and storm approaches and provide a way to extrapolate case studies to global NOx budget.

Acknowledgements. Computer time has been provided by the Institut du Développement et des Ressources en Informatique Scientifique (IDRIS). We thank V.-H. Peuch from MétéoFrance/CNRM/GAME for providing us with the large-scale chemistry fields from the MOCAGE CTM model. This research was supported by the TROCCINOX project funded by the European Comission under the contract EVK2-CT-2001-00122. The authors thank M. Salzmann and A. DeCaria for their very constructive reviews.
