Abstract. Fourier Transform Infrared (FTIR) and X-ray Fluorescence (XRF) were used to measure organic functional groups and elements of submicron particles collected during MILAGRO in March 2006 on three platforms: the Mexico City urban area (SIMAT), the high altitude site at 4010 m (Altzomoni), and the NCAR C130 aircraft. Scanning Transmission X-ray Microscopy (STXM) and Near-Edge X-ray Absorption Fine Structure (NEXAFS) were applied to single particle organic functional group abundance analysis of particles simultaneously collected at SIMAT and C130. Correlations of elemental concentrations showed different groups of source-related elements at SIMAT, Altzomoni, and C130, suggesting different processes affecting the air masses sampled at the three platforms. Cluster analysis resulted in seven distinct clusters of FTIR spectra, with the last three clusters consisting of spectra collected almost exclusively on the C130 platform, reflecting the variety of sources contributing to C130 samples. Positive Matrix Factorization (PMF) of STXM-NEXAFS spectra identified three main factors representing soot, secondary, and biomass burning type spectra. PMF of FTIR spectra resulted in two fossil fuel combustion factors and one biomass burning factor, the former representative of source regions to the northeast and southwest of SIMAT. Alkane, carboxylic acid, amine, and alcohol functional groups were mainly associated with combustion related sources, while non-acid carbonyl groups were likely from biomass burning events. The majority of OM and O/C was attributed to combustion sources, although no distinction between direct emissions and atmospherically processed OM could be identified.

1 Introduction

Atmospheric aerosols have been causing increased concerns during the last few decades since they reduce air quality (Eidels-Dubovoi, 2002), threaten human health (Dockery et al., 1993), and affect climate (Liepert et al., 2004). The effects of organic aerosols remain largely unknown because of their complex composition, especially in urban areas. The Mexico City Metropolitan Area (MCMA) is the second largest megacity in the world. Although its pollution problem has been studied for more than 40 years (Raga et al., 2001), there are only a limited number of organic aerosol measurements (Salcedo et al., 2006; DeCarlo et al., 2008; Aiken et al., 2008). The main sources of MCMA aerosols include biomass burning (Johnson et al., 2006; Salcedo et al., 2006; Molina et al., 2007), motor vehicle emissions, oil burning, and crustal components (Querol et al., 2008; Stone et al., 2008).

The MILAGRO (Megacity Initiative: Local and Global Research Observations) campaign is the largest intensive measurement to date in the MCMA to quantify properties of atmospheric aerosols. This study builds on the measurements presented by Gilardoni et al. (2009) to identify overall statistical trends that span the organic aerosol properties across the MCMA basin. Site-by-site correlations, clusters of organic types, and underlying source-related factors are combined in this work to identify the contributions to organic mass from the major source types in the MCMA. In this work we also establish that the same organic functional group signatures and source types found in bulk submicron samples are evident in external mixtures of internally mixed single particles.

Gilardoni et al. (2009) have shown that the organic mass (OM) measurements from FTIR were well correlated with
simultaneous Aerosol Mass Spectrometry (AMS) measurements during this campaign. Alkane functional groups dominated the OM. The average OM/OC and carboxylic acid COOH to aliphatic saturated C-C-H ratios were higher at Altzomoni than at SIMAT, as a consequence of a larger contribution of oxidized functional groups. The OM was found to correlate with non-soil K, indicating biomass burning being a source of OM in the MCMA.

In this paper, we will extend their work using chemometric techniques and specific statistical tests to identify additional and significant trends in the measurements, in particular for normalized organic functional group composition and fraction of oxidized organic carbon. Correlations of each pair of elements and organic functional groups were investigated. The co-varying of organic functional groups with elemental markers provides an indication of the fraction of organic compound associated with specific metal source signatures. Ward clustering (Ward, 1963) was applied to FTIR spectra to identify the similarities and differences across the three platforms. In addition, PMF was applied to STXM-NEXAFS and FTIR spectra independently to identify the contributions of some general classes of sources to the organic particles. PMF factor time series were correlated to time series of source-specific elements to link factors to the sources that emitted them, in either the gas or particle phase. This work illustrates important differences in the characteristics of the organic mixtures from biomass burning and combustion sources for SIMAT, Altzomoni, and C130 flight measurements, and the analysis quantifies the approximate contribution of each source type to OM in the MCMA and surrounding areas.

2 Methods

Submicron particles were collected on Teflon filters in March 2006, during the MIRAGE (Megacity Impacts on Regional and Global Environments)/MILAGRO field campaign. The SIMAT site is located at the Mexico City Atmospheric Monitoring System building (19°24′12″ N, 99°10′34″ W), and the Altzomoni site is located about 60 km southeast of Mexico City, in the Pass of Cortez between the volcanoes of Popocatépetl and Iztaccíhuatl (19°7′N, 98°38′W; Baumgardner et al., 2009). At SIMAT and Altzomoni, one 12-h samples or three 8-h samples were collected along with one 24-h sample. Samples were collected for 20 min to 1 h on board NCAR C130 at constant altitudes. A field blank was simultaneously collected with each sample. Samples were stored below 0°C after collection before FTIR analysis. The FTIR spectra were quantified as mass concentrations of organic functional groups using an automated algorithm (Russell et al., 2009), including additional calibrations of primary amine functional groups (Appendix A) in addition to standard compound calibrations presented in previous work (Maria et al., 2002, 2003, 2004; Maria and Russell, 2005; Gi-
Potential Source Contribution Function (PSCF; Pekney et al., 2006) analysis was used to determine the most probable potential source regions to each PMF factor. PSCF calculates the probability that a source is located at a particular geographical region. Eight-hour long back trajectories ending at the SIMAT and Altzomoni coordinates were computed each hour at 200 m above ground level for the entire campaign using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Escudero et al., 2006). These trajectories were grouped into periods in which PMF source contributions were either high or low. Periods in which the source contribution for each factor was higher than its 75th percentile value were classified as high periods, and the rest of the periods were classified as low. The trajectories were interpolated into 15-min intervals and superposed on a 4 (latitude) × 4 (longitude) degree domain centered around 30° N, 105° W. The trajectories were classified into periods in which PMF factor spectra with standard reference spectra. Two to eight factors were found to reproduce 85–99% of the total variance. The rotation parameter and the number of factors were explored similarly to PMF of FTIR spectra. FPEAK was set to 0.2, 0, 0.2, and 0.4 for 2 to 8 factors. Two to eight factors were found to reproduce 85–99% of the measured abundances. The 4-factor solution with FPEAK set to 0 produced the most representative results by comparing factor spectra with standard reference spectra.

3 Results

The average OM concentrations at STP were 9.9 µg m⁻³ at SIMAT, 6.6 µg m⁻³ at Altzomoni, and 5.3 µg m⁻³ on the C130 (Gilardoni et al., 2009). Alkane functional groups dominated the total OM, with the mass fractions 47%, 41%, and 73% for SIMAT, Altzomoni, and C130 measurements, respectively. Carboxylic acid functional groups contributed

</table>
30% and 28% to OM at SIMAT and Altzomoni, with a lower fraction of 5% on average for the C130 flights. Alcohol functional groups accounted for 14% of OM at SIMAT, with larger fractions of 19% both at Altzomoni and on the C130. The mass fractions of primary amine functional groups were 9% at SIMAT, 11% at Altzomoni, and 2% on the C130 (Table 1). Of the C130 samples, 87% of amine functional group masses and 73% of carboxylic acid functional group masses were below detection limit, and typically could have accounted for up to 1% and 15% of OM, respectively. FTIR spectra were analyzed for evidence consistent with organosulfate functional groups, but no samples had detectable absorbance at 876 cm\(^{-1}\). Alkene and aromatic functional group masses were below detection limit in all samples of the three platforms, accounting for less than 1% of the average OM. All of the normalized and fractional quantities in the following discussion omit these two functional groups.

The Oxygen-to-Carbon ratio (O/C) can be estimated from FTIR measurements (Russell et al., 2009). The average FTIR O/C was 0.4 for SIMAT, and this value is comparable to the AMS O/C=0.41 at the nearby T0 sampling site (9 km north of SIMAT sampling site) from AMS-based estimates (Aiken et al., 2008). The FTIR O/C was compared with the O/C calculated from quadrupole AMS measurements using the reported ambient relationship for m/z 44 (Aiken et al., 2008; Shilling et al., 2009) for Altzomoni and C130 platforms. At Altzomoni, the FTIR O/C was consistently lower than the AMS O/C, but the differences were within the uncertainties of both FTIR and AMS. On the C130, the FTIR and AMS-based O/C compared well for the samples with carboxylic acid functional groups above detection limit. These comparisons are consistent with the previous study (Russell et al., 2009), showing that the O/C estimates from FTIR and AMS are within the uncertainties associated with inlet transmission. The standard deviations of FTIR O/C were 0.07, 0.12, and 0.18 for SIMAT, Altzomoni, and C130 measurements, respectively. The larger O/C variation during the NCAR C130 flights indicates that the larger altitude and geographic range of these measurements showed greater variability in organic composition than either of the two ground sites.

3.1 Correlations in concentrations

The SIMAT measurements showed correlations of elemental markers from three groups: dust elemental markers (Al, Si, Ca, Ti, Fe) correlated with each other, with correlation coefficients \((r)\) ranging from 0.5 to 0.9; S and Se were correlated with \(r\) of 0.55, indicating coal combustion source types (Qureshi et al., 2006); V and Ni are indicators of oil combustion (Qureshi et al., 2006), they were correlated with \(r\) of 0.87. Concentrations of alcohol, alkane, amine, and carboxylic acid functional groups correlated with each other as well as S, suggesting their common combustion sources. Alkane and carboxylic acid group mass fractions correlated with each other, but they anti-correlated with alcohol group mass fraction, indicating that the alcohol group was dominated by different source types or processes from alkane and carboxylic acid groups.

At Altzomoni, dust elemental markers (Al, Si, Ca, Ti, and Fe) were correlated with each other with \(r\) ranging from 0.6 to 1.0, and combustion elemental markers (V, S, K, Br, Pb, and Se) were correlated with each other with \(r\) ranging from 0.5 to 0.7 (Fig. 1). The high correlations of the dust elemental concentrations may be caused by the single-lane local road, which is located 5 km southeast from Altzomoni site (Baumgardner et al., 2009). Compared to SIMAT and other urban sites (Russell et al., 2009), the combustion-generated components did not fall into clear fuel-specific combustion categories, consistent with higher contributions of more processed or mixed-source organic mass at Altzomoni. This result is also consistent with a higher O/C and OM/OC at Altzomoni than at SIMAT. Similar to SIMAT, concentrations of alkane, amine, and carboxylic acid functional groups at Altzomoni correlated with each other as well as S, likely from industrial or diesel vehicular emissions. Alkane and carboxylic acid group mass fractions were correlated with each other but were anti-correlated with alcohol group mass fractions.

Dust elemental markers (Si, Ca, and Fe) were correlated with each other, with \(r\) ranging from 0.5 to 0.6 for the C130 measurements; Ca also correlated with combustion and industrial markers (S, K, and V) with \(r\) of 0.4, 0.5 and 0.6, respectively, indicating particles from mixed source types. The correlations between organic functional groups and elements were weak, indicating that the particles were mixed or processed during atmospheric transport, leaving no clear source signature. Concentrations of alcohol and alkane functional groups correlate with each other, but the mass fractions of alcohol and alkane functional groups were anti-correlated.
3.2 Cluster analysis of FTIR spectra

Cluster analysis was used to identify similarities among the measured normalized FTIR spectra. The Ward-type cluster analysis method was used and two to ten branches were tested. Spectra from the C130 measurements were separated from the Altzomoni and SIMAT spectra at the first branch; Altzomoni spectra started to be separated when five or more branches were used. Seven clusters were used to best represent different types of FTIR spectra associated with different organic functional group compositions (Fig. 2). Using more than seven clusters resulted in small clusters consisting of only two C130 spectra, which were not statistically significant.

Clusters I, II, and III were the dominant clusters, as they contained 65% of the spectra. Seventy-percent of the spectra from clusters I and III were from SIMAT and the other 30% were from Altzomoni, with the difference between these two clusters being the presence of sharper peaks in the alkane functional group region of cluster III spectra. Samples from cluster III also had the lowest O/C among clusters I–IV. Forty-percent of the spectra in cluster II were from SIMAT and 45% from C130 measurements. The C130 samples in this cluster were collected at lower altitudes and closer to the Mexico City basin than the samples in the other clusters, indicating these samples were influenced by the city outflow. Samples from this cluster had the largest alkane functional group fraction among clusters I-IV. The similarities among spectra from different platforms suggest that many of the sources were associated with region-wide pollution that was transported in air masses sampled by all three platforms, which is consistent with the findings of Baumgardner et al. (2009). 85% of the spectra in cluster IV were from Altzomoni and 15% from SIMAT. The average O/C of the samples in cluster IV was significantly higher (at a 95% confidence level) than O/C of the samples in the other clusters, and samples from this cluster had the largest alcohol functional group fraction among all clusters. Clusters V, VI, and VII consisted almost exclusively of C130 spectra, with only 5% of the spectra from Altzomoni in cluster V. The three distinct branches of clusters of C130 measurements separated from the ground site measurements indicates the wide variety of different sources and air masses sampled by the C130.

3.3 Positive matrix factorization of FTIR spectra

PMF was applied to the FTIR spectra of the three platforms (“combined PMF”) and spectra from each site separately (“separate PMF”) using three to six factors. By investigating factor chemical compositions, time series, and their possible source regions, similar factors were identified from both “combined PMF” and “separate PMF”, indicating similar sources and regional pollution in the MCMA. The five- and six-factor solutions resulted in correlated factors with similar compositions and source regions, indicating some factors split into smaller but indistinguishable components because too many factors were used given the size of the data.
Table 2. Correlations of PMF factors to elements with $r>0.5$ (bold) and $0.25<r<0.5$, average organic mass concentrations $\mu g\, m^{-3}$, and pie charts of organic functional group mass contributions by sampling platforms. Colors indicate alkane (blue), alcohol (pink), carboxylic acid (green), amine (orange), and non-acid carbonyl (teal) functional groups.

The first factor was persistent in all PMF runs and was identified as a biomass burning factor, since the OM of this factor increased significantly during the fire period (12–14 March 2006) at 99% confidence level, while the other factors did not show strong correspondence with the fire period. The fire period was identified by Aiken et al. (2009) by measuring biomass burning tracers including potassium, levoglucosan, and acetonitrile at the T0 site. This result is consistent with the effects of biomass burning events on the organic mass concentrations of Mexico City described elsewhere (Moffet et al., 2008b; Gilardoni et al., 2009). PSCF of this factor showed that the potential source of this factor was located south of the SIMAT and Altzomoni measurements (Fig. 5a, c) in the mixed forest region (Yokelson et al., 2007). This source region also matches well with the possible source region of aged biomass burning particles described by Moffet et al. (2008b) from single particle analysis. Non-acid carbonyl functional groups dominated this factor, accounting for 26–47% of the OM. The OM contribution of this factor at SIMAT was comparable to the OM contribution of this factor at Altzomoni, indicating that biomass burning had a regional influence during the MILAGRO campaign.
Fig. 3. OM concentrations of northeast combustion (green), biomass burning (red), and southwest combustion (blue) factors for SIMAT (a), Altzomoni (b), and C130 (c) samples.

Fig. 4. Average contributions of (a) OM concentrations and (b) O/C of northeast combustion (green), biomass burning (red), and southwest combustion (blue) factors for SIMAT, Altzomoni, and C130 platforms.

with S, Se, Cu, Zn, Fe, and Mn. These elements can be attributed to various combustion processes, for example, S could be emitted from industrial or motor vehicular combustions using fossil fuels (Flore et al., 1999). The other sources of these elements could also include oil burning, coal burning, and solid waste incineration (Sharma et al., 2005; Li et al., 2004; Balasubramanian et al., 2004; Finlayson-Pitts et al., 2000). The combustion sources around Mexico City include incineration (Moffet et al., 2008a), oil combustion (Flore et al., 1999; Moffet et al., 2008b), motor vehicle emissions (Vega et al., 1997; Chow et al., 2002; Querol et al., 2008; Stone et al., 2008), and local charcoal burning (CICA, 1999), which can produce the elements associated with these three factors. While some studies show diurnal trends and weekday or weekend variations of OC (Stone et al., 2008), none of these factors were found to have these patterns. As a result, there were insufficient constraints to separate these factors by specific source types. The similarities of the trace metal signatures and the variety of fuels used in Mexico City did not allow us to identify a single, specific fuel type associated with these combustion sources.

The air mass back trajectories and OM concentrations provide some information about the differences among the combustion type factors. PSCF showed high OM concentrations of two of the combustion factors originated from similar source regions, and both of these factors correlated with dust markers (Al, Si, Ca, and Ti) at the Altzomoni site in addition to the combustion markers noted above. These common features provided evidence that both of these factors came from very similar and collocated sources. For these reasons, these two factors were combined to represent a “northeast combustion” factor, since they were associated most strongly with northeastern sources, likely from the industrial areas located at the northeastern MCMA (Fig. 5b, e; Johnson et al., 2006; Moffet et al., 2008b). The combined factor had stronger correlation with S than the individual uncombined factors.
Alkane functional group dominated this factor, accounting for 30–40% of the OM. At SIMAT, alcohol and carboxylic acid group fractions of this factor were comparable, accounting for 19% and 21% of the OM, respectively. At Altzomoni, alcohol group was a larger contributor to OM (37%) than carboxylic group (19%). This factor had the largest OM among all factors.

The factor associated with a strong source region located to the southwest of SIMAT (Fig. 5c) close to the city of Toluca was denoted as the southwest combustion factor. Toluca is the capital city of Mexico State. Toluca has reduced air quality due to recent, rapid industrial growth (Aldape et al., 2008). The source region also tracked the freeways connecting Toluca and Mexico City, including freeways MEX 15 and MEX 134. Freeway 5 was also identified as a potential source. PSCF at Altzomoni showed the source region was near freeway MEX 95D (Fig. 5f). This factor represented industrial and motor vehicular emissions. Similar to the “northeast combustion” factor, alkane group dominated this factor but had a larger fraction of 44–51%. Carboxylic acid group was the second largest component in this factor, accounting for 29–34% of the OM.

3.4 PMF and clusters of STXM-NEXAFS spectra

Three factors were consistently observed in 80% of all PMF runs. These factors were interpreted by comparing them with reference STXM-NEXAFS spectra of pure compounds and typical types of STXM-NEXAFS spectra identified in atmospheric particle measurements described by Takahama et al. (2007).

The first factor spectrum showed ketone and alkene group absorption peaks at 285 eV and 287.7 eV. This factor was identified as a soot factor, as the shape of this factor spectrum was comparable to the soot type spectra (Fig. 6a) described by Braun et al. (2005) and Hopkins et al. (2007). The second factor spectrum was dominated by a strong carboxylic acid absorption peak at 288.7 eV and shared similarities with the spectra of category (a) described by Takahama et al. (2007; Fig. 6b). Particles in category (a) are likely to be secondary organic aerosol formation. Factor 3 compared well with the STXM-NEXAFS spectrum for fulvic acid (Fig. 6c; Ade et al., 2002). Fulvic acid in atmospheric particles are likely to originate from biomass burning events (Tivanski et al., 2007), thus this factor was identified as a biomass burning factor. The 4-factor solution with a rotation of 0 resulted...
in the most representative results. This solution contained the three main factors identified above and an additional factor, which was present in only a few particles. The three main factors accounted for 80% of the particles analyzed by STXM-NEXAFS for the SIMAT and C130 during MILAGRO.

STXM-NEXAFS spectra were grouped into “secondary” type, “biomass burning” type, and “soot” type spectra described by Takahama et al. (2007). Figure 7 summarizes the size distributions of analyzed particles and the average fractions of the three major factors within each size range. The “secondary” type particles were in the size range of 0.2–5 µm, while the “biomass burning” and “soot” type particles were in the size range of 0.1–10 µm. The “soot” type particles were the most abundant, and 70% of these particles have diameters falling between 0.2 and 1 µm. The soot factor was the largest factor for particles smaller than 1 µm, and its fractions were lower in large size ranges. The biomass burning factor showed an increased fraction from submicron to supermicron size ranges.

4 Discussion

In this section, we consider how the organic mass and oxygenated fraction of organic mass are affected by diurnal trends at three platforms. We also use the FTIR spectral clusters to highlight the differences observed among the three platforms. Our PMF analysis provides a way to link some of these differences in measurements from the three platforms to the types of sources that affect each. In addition, we compare and contrast our results from STXM-NEXAFS spectra from single particle measurements and FTIR spectra from submicron bulk particle samples.

4.1 Diurnal trend of functional groups and elements

Samples were divided into “morning”, “afternoon”, and “night” categories according to the sampling time to investigate the differences of organic functional groups and elements as a function of time of day. Tukey’s Honest Significant Difference method was applied to calculate the differences of the mean concentrations among the categories at a 90% confidence level.

At SIMAT, concentrations of OM, alkane, and carboxylic acid functional groups were found to be significantly higher in the morning than in the afternoon or at night. The high OM and organic functional group concentrations could be explained by either the emission of compounds containing alkane and carboxylic acid functional groups by traffic in the morning or by the low boundary layer in the early morning (Shaw et al., 2007). OM/OC and O/C was significantly higher in the afternoon, indicating that photochemical processes may contribute to the oxidation of organic compounds in the afternoon. Fractions of alcohol and carboxylic acid functional groups had higher values at night than in the afternoon, likely indicating the relative reduction of alkane functional groups and the concomitant accumulation of oxygenated compounds emitted and produced during the day.

At Altzomoni, concentrations of alkane groups, carboxylic acid groups, amine groups, Se, V, K, and S were found to be higher during the day than at night. Back trajectories at Altzomoni showed that the air masses mainly came from the east and southeast during daytime. The city of Puebla, which is located approximately 50 km east of Altzomoni, is the fourth most populous city in the country and has intense vehicular traffic as well as an important industrial zone in its metropolitan area (Juarez et al., 2005). The boundary layer can reach as high as 6 km during the day (Shaw et al., 2007), which is higher than the 4010 m location of the Altzomoni site. The elevated concentrations of those species during the day may be caused by the transport of pollutants from Puebla. During the night, the boundary layer decreased, and the site was influenced by air masses in the free troposphere, resulting in low concentrations.

No significant differences were found between the morning and afternoon for the C130 measurements, which is not surprising as the measurements were sparse and the sampling location for each observation varied on this mobile platform. While other studies have found that there were coarse particle concentration differences between weekdays and weekends (Stephens et al., 2008), differences in submicron organic functional group and elemental concentrations between days of the week were not found in this study for any platform.

4.2 FTIR spectral clusters and O/C

The shapes of spectra in cluster II are comparable to the spectral shapes in cluster S1 identified in shipboard measurements during TexAQS/GoMACCS 2006 near Houston (Russell et al., 2009). Sample spectra in cluster S1 were mainly from the relatively clean southerly flow from the Gulf or polluted by some nearby land-based sources. The similarities of the spectra from different geographical locations indicate that there are some common sources or processes occurring in the atmosphere.

Cluster I and cluster III mainly consist of spectra from SIMAT and Altzomoni, reflecting the similarities of submicron organic composition at these two platforms during certain time periods. Back trajectories at Altzomoni showed that air masses mainly came from northeast, east, and southeast of the site for samples in cluster I and cluster III, indicating the influence of urban pollution from Puebla, including vehicular and industrial emissions (Juarez et al., 2005). It is possible that the transport of Puebla plumes to Altzomoni resulted in organic particles with similar composition at Altzomoni and SIMAT.

Alkane, carboxylic acid, and alcohol groups were the main functional groups in particles and they accounted for more
than 80% of OM for three platforms. Figure 9 shows the
distributions of clustered spectra as a function of alkane, car-
boxylic acid, and alcohol group mass fractions. At SIMAT,
the clustered spectra were relatively centered on the triangle
plot, showing comparable mass fractions of the three main
functional groups. At Altzomoni, cluster IV was separated
from other clusters. Samples from cluster IV showed high al-
cohol group concentrations, and the highest O/C. This cluster
mainly consisted of Altzomoni samples (Fig. 2), which were
collected during times when the wind direction was from the
north or northwest (Gilardoni et al., 2009), suggesting that
cluster IV spectra may be associated with processed particles
that originated in Mexico City.

### 4.3 PMF factors and associated sources

PMF factors attributed alkane, carboxylic acid, amine, and
alcohol groups largely to combustion type sources. Industrial
combustion and motor vehicular emissions are the most pos-
sible combustion sources in the MCMA (Stone et al., 2008;
Johnson et al., 2006). This result supports the findings that
direct emission processes, such as gasoline combustion and
oil burning are sources of alkane and carboxylic acid groups
in atmospheric particles (Rogge et al., 1993; Oros et al.,
2000). Amines have also been suggested to originate from
motor vehicle exhaust and industrial processes (Murphy et
al., 2007). PMF attributed the main source of amine to com-
bustion sources, which is consistent with the possible indus-
trial sources discussed by Moffet et al. (2008b). Volatile
organic compounds emitted from motor vehicles can form
alcohol groups during photochemical processes (Sax et al.,
Average fractions of processed (orange), soot (black), and biomass burning (grey) factors in cluster categories for “processed” (orange), “soot” (black), and “biomass burning” (grey). (b) Average fractions of processed (orange), soot (black), and biomass burning (grey) factors in 0.1–0.2 µm, 0.2–0.5 µm, 0.5–1 µm, 1–2 µm, 2–5 µm, and 5–10 µm size ranges for 4-factor PMF run of STXM-NEXAFS spectra.

Fig. 7. (a) Size distributions of single particles for processed type (corresponding to category a), soot type (corresponding to categories b, c, d, e, g, h, and m), and biomass burning type (corresponding to categories i and j) particles described by Takahama et al. (2007) from cluster analysis of STXM-NEXAFS spectra. Colors indicate STXM-NEXAFS cluster categories for “processed” (orange), "soot” (black), and “biomass burning” (grey). (b) Average fractions of processed (orange), soot (black), and biomass burning (grey) factors in 0.1–0.2 µm, 0.2–0.5 µm, 0.5–1 µm, 1–2 µm, 2–5 µm, and 5–10 µm size ranges for 4-factor PMF run of STXM-NEXAFS spectra.

While the single-particle STXM-NEXAFS spectra were sparse in terms of particle number and sampling times, the submicron particle types that were frequently identified were expected to have some organic components that were similar to the composition of submicron particle mass collected on bulk filters. PMF of both single and bulk particle spectra resulted in biomass burning and combustion type factors. Figure 8b shows the fractions of the northeast combustion factor, the southwest combustion factor, and the biomass burning factor of FTIR samples from SIMAT and C130 platforms. Clusters V, VI, and VII (exclusively consisted of C130 samples) were separated from the other clusters. Clusters II and III were separated: cluster II was associated with larger southwest combustion factor fractions, while cluster III was associated with greater northeast combustion factor fractions. Results from single particle spectra showed that the soot type particles were separated from biomass burning type particles (Fig. 8a). This indicates some clusters of both single particle spectra and bulk particle spectra were source-related.

Figure 8a shows that the contributions of soot and biomass burning factors to each ambient particle spectrum varied, but most particles showed consistent contributions from processing. The secondary factor accounted for 10–60% of the carbon absorbance, while the fractions of the other two factors showed a larger variation ranging from about 0–80% and 0–90%, suggesting the biomass burning and soot factors were more source-related, while the secondary factor had a consistent contribution to most particles. Figure 8b shows that 85% of the samples had southwest factor fraction of OM between 30 and 65%, while the northeast factor fraction of OM varied from 20 to 70%. Both results show that the factors associated with processed component was more consistent during the sampling period than the combustion factors, since they had a smaller range of contribution for most particles.

5 Conclusions

Organic mass concentrations were 9.9 µg m^{-3}, 6.6 µg m^{-3}, and 5.3 µg m^{-3} for SIMAT, Altzomoni, and C130 flight measurements. Alkane functional group concentrations dominated the OM, with the fractions ranging from 41% to 73%. Dust markers (Ca, Fe, and Si) correlated with each other for all three platforms, while combustion type elements showed different correlations among the three platforms. At SIMAT, two source-related groups of elements were identified: coal combustion type elements (S and Se) and V and Ni from oil combustions; while at Altzomoni, elements from several types of fossil fuel combustion (V, S, K, Br, Pb, Se) correlated with each other. For the C130 measurements, Ca was found to correlate with S, K, and V. The differences in
correlations of elements among the three platforms suggest that the urban area was more influenced by fresh emissions, while the high altitude site was more influenced by mixed sources or atmospheric (photochemical) processing.

The cluster analysis of FTIR spectra showed both similarities and differences among the three platforms. Seven distinct clusters of FTIR spectra were identified, from which the last three clusters consisted almost exclusively of samples collected aboard the C130 research flights based in Veracruz, indicating the wide variety of different sources and air masses sampled by the C130. More than 80% of SIMAT spectra and more than 70% of Altzomoni spectra are identified as clusters I and III, while cluster IV consists almost exclusively of Altzomoni spectra with high alcohol group fractions. The easterly and southeasterly transport of Puebla pollutants to Altzomoni may result in the similarities of organic particles from Altzomoni and SIMAT, while the distinct cluster IV of Altzomoni samples with high O/C suggests more processed particles at the Altzomoni site than at the SIMAT site.

PMF analysis was applied to STXM-NEXAFS spectra and FTIR spectra. PMF of STXM-NEXAFS spectra resulted in three main factors, which represented biomass burning, secondary, and fossil fuel combustion type spectra. PMF of FTIR spectra resulted in one biomass burning factor and two combustion factors, which were not attributed to specific

source types as a consequence of the complexity of emission sources in the MCMA. The two combustion type factors were separated by potential source regions: one of them (the northeast combustion factor) was strongly associated with industrial sources to the northeast of SIMAT in the MCMA, and the other (the southwest combustion factor) could represent industrial and motor vehicular emissions mainly from the vicinity of City of Toluca. The southwest combustion factor has significant OM contributions from processed components, but a separate “processed” component was not identified. Several trends in composition were consistent for the factors and rotations selected. Combustion was the largest source of both OM and O/C. PMF attributed alkanes, carboxylic acid, amine, and alcohol functional groups largely to combustion sources, among which industrial and motor vehicular emissions were the most probable contributors. Biomass burning contributed to a small fraction (0.8%) of submicron particle mass. Non-acid carbonyl groups, which could be emitted as breakdown products during lignin or other biomass burning (Simonet et al., 1999), dominated this factor. Both PMF of single particle STXM-NEXAFS spectra and PMF of submicron FTIR spectra showed that the clusters were associated with different fractions of the factor contributions. Narrower ranges of the fraction of the processed factor contributions to single particles and submicron OM (10 to 60% from PMF of single particle spectra and 35 to 60% from PMF of submicron OM spectra) than combustion type factors suggests that the combustion factors (0–90%) varied more with local sources, while the factors related to atmospheric processing were more constant during the campaign.

Appendix A

FTIR calibrations of amine functional groups

Calibrations of organic functional groups of FTIR spectra were conducted using the measured absorption per mole of each component from laboratory-generated standards (Maria et al., 2002). Three primary amine standards (n-Tridecylamine, n-Tetradecylamine, alanine) and three secondary amine standards (N-Methyl-n-octadecylamine, Di-n-decylamine, Di-n-dodecylamine) were used to quantify amine functional group absorption at 1625 cm\(^{-1}\) observed in our ambient particle spectra. Results showed that secondary amines do not have detectable absorption peaks at 1625 cm\(^{-1}\). Alanine was used as the standard for quantification of primary amine groups as it best represents the absorption peak at 1625 cm\(^{-1}\). The revised guided algorithm (Russell et al., 2009) was applied to do peak fitting and integration of alanine standard spectra. The absorptivity of amine functional group is 0.12 \(\mu\)mol/unit of peak area with a linear fit \((R^2=0.97)\) of absorption and moles per functional group. Deviations from this absorptivity were not observed for mixtures of alanine and ammonium sulfate. Possibilities of absorption at 1625 cm\(^{-1}\) by organonitrile compounds were ruled out by the absence of absorption at 1280 cm\(^{-1}\) in the ambient FTIR spectra (Mylonas et al., 1991; Allen et al., 1994; Garnes et al., 2002; Laurent et al., 2004). Water absorption at 1625 cm\(^{-1}\) is removed by purging the sample chamber of FTIR instrument for 3 min before scanning each sample.
