Methane and nitrous oxide emissions in The Netherlands: ambient measurements support the national inventories

S. van der Laan, R. E. M. Neubert, and H. A. J. Meijer

Centre for Isotope Research, University of Groningen, Groningen, The Netherlands

Abstract. We present net emission estimates of CH$_4$ and N$_2$O of The Netherlands based on measurements conducted during the period of May 2006 to April 2009 at station Lutjewad, The Netherlands ($6^\circ21^\prime$ E, $53^\circ24^\prime$ N, 1 m a.s.l.). $^{222}$Radium mixing ratios were applied as an indicator for vertical mixing and long-range air mass transport and used to calculate the net surface fluxes from atmospheric mixing ratios of CH$_4$ and N$_2$O. Our study shows that our measurement site Lutjewad is well-suited to measure emissions from The Netherlands and validation of the national inventories using the $^{222}$Radium flux method. Since this study is purely observation-based it is independent from inventories or atmospheric models. Our results are compared to the national inventories as reported to the UNFCCC. We found net emissions of: ($15.2\pm5.3$) t km$^{-2}$ a$^{-1}$ for CH$_4$ and ($0.9\pm0.3$) t km$^{-2}$ a$^{-1}$ for N$_2$O. These values are lower than the inventory-based emissions (2006-2008 averages) of ($18.3\pm3.3$) t km$^{-2}$ a$^{-1}$ for CH$_4$, and ($1.3\pm0.6$) t km$^{-2}$ a$^{-1}$ for N$_2$O, but the differences are insignificant.

1 Introduction

In the face of the recent and predicted climate changes, most nations joined an international treaty: the United Nations Framework Convention on Climate Change (UNFCCC). The goal of this treaty is to reduce global warming and to determine measures for adaptation to temperature increases which are inevitable. Of major concern to the UNFCCC is the rapid increase of the long-lived greenhouse gases (LL-GHGs) carbon dioxide (CO$_2$), methane (CH$_4$), nitrous oxide (N$_2$O) and halocarbons (a group of gases containing fluorine, chlorine and bromine). Their radiative forcing (RF) in 2005 as compared to pre-industrial times was estimated to be respectively: ($1.66\pm0.17$) W m$^{-2}$, ($0.48\pm0.05$) W m$^{-2}$, ($0.16\pm0.02$) W m$^{-2}$ and ($0.34\pm0.03$) W m$^{-2}$ (Forster et al., 2007). These gases are significantly contributing to the total positive RF contributions of around 3.2 W m$^{-2}$.

In order to quantify the major sources of the GHGs, to monitor the national emissions and verify the effects of national reduction policies, UNFCCC partners commit themselves to annually report their greenhouse gas emissions. These reports are based on estimations of the amount of GHG sources (e.g. traffic, agriculture) and sinks (e.g. forest growth) and the amount of greenhouse gases they produce or take up (emission factors) when active. This method is therefore highly dependent on the accuracy and completeness of the emission data. Inventories strongly rely on statistics of for example cattle, traffic and energy consumption of factories which are usually provided by the individual sources. On top of that assumptions are needed concerning the amount of greenhouse gases an individual source emits when active: the applied emission factors which most likely contain (systematic) errors. In order to cope with the uncertainties related to the inventory method, parties are encouraged by the UNFCCC to develop and implement an independent validation system based on atmospheric measurements.

Our study focuses on estimating the net surface emissions of CH$_4$ and N$_2$O in The Netherlands from ambient mixing ratios of CH$_4$, N$_2$O and $^{222}$Radon ($^{222}$Rn), to provide such an independent validation of the national inventories. Furthermore, we are interested if we can also estimate the surface emissions of the neighbouring countries Germany and Belgium.

In order to determine surface emissions of CH$_4$ and N$_2$O from their ambient mixing ratios $^{222}$Rn is used as a reference tracer for atmospheric mixing and transport (Levin, 1984; Thom et al., 1993; Schmidt et al., 1996). $^{222}$Rn is a radioactive noble gas (its radioactive half-life is 3.825 days) which is produced at a constant rate from $^{226}$Radium which
is relatively uniformly distributed in all soils. When released to the atmosphere, $^{222}$Rn experiences the same atmospheric circumstances (transport and mixing) as any other constituent. Hence, when the surface emanation of $^{222}$Rn is known, the surface emission of a certain constituent can be determined from the changes in mixing ratios of this constituent and $^{222}$Rn. Using $^{222}$Rn to determine surface fluxes from mixing ratios has already been successfully applied in other studies e.g. to: CO$_2$ (Levin, 1987; Gaudry et al., 1990; Schmidt et al., 2003), N$_2$O (Schmidt et al., 2001; Wilson et al., 1997), CH$_4$ (Thom et al., 1993; Schmidt et al., 1996; Levin et al., 1999), CFCs (Biraud et al., 2002), peroxyacetyl nitrate (Schrimpf et al., 1996) and NO and NO$_2$ (Rohrer et al., 1998). New aspects of our study are related to the aimed-at catchment area of the emissions (in our case we focus mainly on The Netherlands), and our data selection method. The latter aims at locating individual sources or source areas instead of analyses of daily, weekly or monthly averaged data. We further propose a small improvement in the $^{222}$Rn decay correction when dealing with emissions from large distances. Also, we apply data from a newly available European $^{222}$Rn soil emission map based on a network of gamma dose rate measurements (Szegvary, 2007). To account for the fact that the net emissions are positive (i.e. from surface to atmosphere) and the method is highly sensitive to nearby emissions we use a lognormal regression fit to estimate the annual surface emissions of CH$_4$ and N$_2$O.

Our results are based on semi-continuous measurements of ambient mixing ratios of CH$_4$, N$_2$O and $^{222}$Rn which were performed at our atmospheric measurement station Lutjewad during the period May 2006 to March 2009. The applied instrumentation is described in Sect. 2. In Sect. 3 the data selection routine and the method for the calculation of the surface fluxes is described. Finally, in Sect. 4 our purely observation-based results are compared to the emission inventories of The Netherlands and its surrounding countries as reported to the UNFCCC.

2 Measurement site Lutjewad and applied instrumentation

2.1 Site description

Station Lutjewad is situated on the Dutch North Sea coast (see Fig. 1) at 53°24’18” N, 6°21’13” E, 1 m a.s.l. The station is about 30 km to the Northwest of the city of Groningen. The station is equipped with a 60 m tall tower which has air intakes at the top, from where ambient air is continuously flushed down to a laboratory where the analyses take place. The tower is equipped with basic meteorological equipment, measuring air temperature, humidity, atmospheric pressure, wind-speed and -direction and solar radiation. As the station is normally unmanned, all equipment is designed to operate fully automated and data are sent on a daily basis to our institute in Groningen (Van der Laan et al., 2009).

Wind direction at the site is mostly southwest and west (Fig. 1). With northerly winds, the sampled air can be characterized as having background mixing ratios. With wind directions between approx. 40°–240° air masses with continental contributions are sampled. During the period between May 2006 and April 2009 the prevailing wind direction (31% of all data) was between 195° and 255°. Most abundant wind speeds are found between 6 m s$^{-1}$ and 9 m s$^{-1}$. About 35% of all wind speeds were found in this range.

![Wind conditions at station Lutjewad (measured at 60 m) for the period of May 2006 to April 2009 (map produced under creative commons license by Planiglobe.com). Bin size is 15 degrees and the north is pointing up. The prevailing wind direction, about 31% of all time, is between 195° and 255°. Most abundant wind speeds are found between 6 m s$^{-1}$ and 9 m s$^{-1}$. About 35% of all wind speeds were found in this range.](image)

2.2 Atmospheric CH$_4$ and N$_2$O measurements

Ambient air is continuously collected from an air intake at 60 m height and immediately dried (up to 50% reduction in humidity) using a Nafion membrane drier (MD 110-72-S, Perma Pure, Toms River, New Jersey). The pre-dried air is subsequently pumped down through polyethylene/aluminium tubing (1/2” O.D., Synflex 1300, Eaton, Gembloux, Belgium) to the laboratory where analyses by a modified Agilent HP 6890N Gas Chromatograph (GC) take place. The total travel time from the inlet to the GC is about...
We derive the surface emission rates of CH$_4$ and N$_2$O from their ambient mixing ratios by using $^{222}$Rn as a reference tracer for atmospheric mixing and transport (Levin, 1984; Thom et al., 1993; Schmidt et al., 1996). $^{222}$Rn is a radioactive noble gas (its radioactive half life is 3.825 days) which is produced at a constant rate by the decay of $^{226}$Ra (Radium), which is present in all soils and is relatively uniformly distributed. Via the soil air, radon is emitted into the atmosphere where it is only subjected to radioactive decay and dilution by atmospheric transport (e.g. mixing with the free troposphere under unstable atmospheric conditions). With knowledge of the transit time, the $^{222}$Rn in a given air mass can, theoretically, be corrected for radioactive decay, transforming $^{222}$Rn to an ideal conservative tracer. Since the dilution by atmospheric mixing is the same for $^{222}$Rn as for any other tracer, in our case CH$_4$ and N$_2$O, the surface emissions of CH$_4$ and N$_2$O can be determined from their mixing ratios and the mixing ratio of $^{222}$Rn, provided the original $^{222}$Rn soil flux is known, remains constant and is homogenous for the spatial and temporal scale of influence. The surface flux of a given tracer $x$ is then given by:

$$\Phi_x = \Phi_{Rn} \frac{\Delta C_x}{\Delta C_{Rn}}$$

Herein $\Phi_x$ represents the estimated surface flux of a tracer $x$, $\Phi_{Rn}$ is the $^{222}$Rn soil flux rate, $C_x$ is the atmospheric mixing ratio of a tracer $x$ and $C_{Rn}$ is the atmospheric mixing ratio of $^{222}$Rn. The $\Delta$'s represent departures from their background values. The over-bars represent the means for the spatial and temporal scales of influence. One of the main underlying assumptions of the $^{222}$Rn flux method is that both the surface emissions of $^{222}$Rn and the tracer of interest are homogeneously spread over the area that is influencing the measurements (catchment area). This, however, is not always the case. For example, CH$_4$ can be emitted at a certain moment from a point source and then transported to our mast. During this travel there will be a continuous addition of $^{222}$Rn from the surface (the magnitude of this addition will depend on the soil type of the surface) but not of CH$_4$. Thus, the method is less suited for the detection and strength analysis of individual point sources and more uncertain for catchment areas which are very heterogeneous.

3.1 Estimation of surface emissions from ambient mixing ratios

We derive the surface emission rates of CH$_4$ and N$_2$O from their ambient mixing ratios by using $^{222}$Rn as a reference tracer for atmospheric mixing and transport (Levin, 1984; Thom et al., 1993; Schmidt et al., 1996). $^{222}$Rn is a radioactive noble gas (its radioactive half life is 3.825 days) which is produced at a constant rate by the decay of $^{226}$Ra (Radium), which is present in all soils and is relatively uniformly distributed. Via the soil air, radon is emitted into the atmosphere where it is only subjected to radioactive decay and dilution by atmospheric transport (e.g. mixing with the free troposphere under unstable atmospheric conditions). With knowledge of the transit time, the $^{222}$Rn in a given air mass can, theoretically, be corrected for radioactive decay, transforming $^{222}$Rn to an ideal conservative tracer. Since the dilution by atmospheric mixing is the same for $^{222}$Rn as for any other tracer,
which can increase steadily over several days, indicating a long continental influence. This can be seen in the right part of Fig. 2. When regional atmospheric conditions are such that a new event is formed, these events are assumed to be influenced mostly by regional surface emissions. In Fig. 2 the first of such an event is indicated with a 2. However, in order to be representative for short-range surface fluxes we have to take into account their new baseline. Therefore we subtract from these peaks the starting value (of the mixing ratios) for each individual peak. In Fig. 2 we illustrated this with the dashed lines.

For how long an air mass has been travelling from the emission's source(s) will depend on the meteorological circumstances (i.e. wind speed or changing wind direction). But, provided these circumstances remain stable, we can assume this transit time is the same for the whole air mass which is collected during an event. Therefore we assume the length of an event can be used as an indicator for the area of influence. For example, since the first event in Fig. 2 has a total duration of about 13 h and the average wind speed is about 7 m s\(^{-1}\), we estimate that the maximum distance of influence is about 330 km from our station which, in this direction, is just outside the Dutch border. Therefore, we will classify this event, as well as the following two (smaller) events, as a short-range event and assume it is mainly influenced by surface emissions from The Netherlands. The following event was not selected because the wind direction indicated a non-Dutch origin of these air masses. In our quest, to select only events which are influenced mainly by Dutch surface emissions (and not from the near surroundings of our tower or abroad), we selected only events which endured at least 4 h and at most 17 h. Then, back trajectories were made of all events using the Hysplit 4 lagrangian back trajectory model (Draxler and Rolph, 2003). For each individual event, back trajectories were calculated corresponding to the total duration of the event, i.e. if an event sustained for 8 h, we calculated its trajectory 8 h back in time. As the starting point of the back trajectory we used the last data point of an event (before vertical mixing was re-established). Back trajectories starting in the middle of an event were also made in order to validate steady state conditions during travel. In this way we tried to estimate the main area influencing the measurements during the course of an event. Events were only accepted for further analyses if the trajectories indicated that the track of the air mass was mainly (approx. >70%) over The Netherlands and thereby suggesting that these events were dominantly influenced by Dutch emissions. Figure 3 shows hourly points on the trajectories of the events which were selected for further analysis.

A linear least square regression fit between the half hourly averaged observations of CH\(_4\) and \(^{222}\)Rn, and N\(_2\)O and \(^{222}\)Rn is made for each individual event. An example is shown in Fig. 4a and b for an event starting on 18 August 2006.
Fig. 4. (a) Example of a regression slope between CH\textsubscript{4} and 222Rn determined from a single event starting at 18 August 2006 19:30 LT and ending at 08:00 LT the next day. 222Rn increased by about 2 Bq m\textsuperscript{-3} during this period and CH\textsubscript{4} by about 170 ppb. (b) Similar to (a) but now for N\textsubscript{2}O which increased by about 4.5 ppb in the same time.

During the event the mixing ratio of 222Rn increased by about 2 Bq m\textsuperscript{-3} during this period and CH\textsubscript{4} by about 170 ppb. In the same time the mixing ratio of N\textsubscript{2}O increased by about 4.5 ppb. For both regression slopes a high correlation was found between 222Rn and the other tracer.

Making linear regression fits for each individual event, instead of for example weekly or monthly averaged data, enables us not only to estimate the source areas (and thus filter out events which are highly influenced by emissions from abroad) but also gives a higher temporal resolution. However, with so few data points (typically in the order of about 15-25) the fits can only be used if a high correlation between the two mixing ratios is found. A high correlation factor is not always expected since CH\textsubscript{4} and especially N\textsubscript{2}O can also originate from temporary point sources. The regression fits were evaluated by making histograms of their regression coefficients, see Fig. 5. We decided to use a minimal correlation coefficient of $R=0.7$ as a limit for further analyses in order to maintain regression slopes with a sufficient correlation (the method assumes a correlation between 222Rn and CH\textsubscript{4}/N\textsubscript{2}O and still maintain enough events to determine annual averages.

Additional to all events which are assumed to represent the national emissions, we obtained a so-called long-range dataset. This dataset contains events which are believed not
to represent emissions from The Netherlands (i.e. those used in the short range analysis), as well as well-mixed background mixing ratios and slow increases over several days from this background. From this dataset we excluded all data with wind directions from 280°–40° (marine sector) and determined the regressions slopes from monthly binned mixing ratios.

In order to estimate annual emissions from the individual fluxes usually a median (Rohrer et al., 1998) or (monthly) mean (Levin, 1987; Gaudry et al., 1990; Thom et al., 1993; Schmidt et al., 1996, 2001, 2003; Schrumpf et al., 1996; Wilson et al., 1997; Levy et al., 1999; Biraud et al., 2000; Messager et al., 2008) is used. However, since the ambient measurements are very sensitive for nearby source emissions, annual emission estimates using a median or a (Gaussian) mean would probably be overestimated. Therefore, we decided to use a lognormal distribution which is less sensitive for very high values and thus less sensitive for the nearby sources. A lognormal distribution is furthermore reasonable since the emissions are directed from the surface to the atmosphere and are therefore positive in sign.

3.3 Correction for radioactive decay of 222\textsuperscript{Rn}

The measured mixing ratios of (e.g.) CH\textsubscript{4} and 222\textsuperscript{Rn} during an event are influenced by the same conditions (i.e. vertical mixing, dilution) but additionally the mixing ratios of 222\textsuperscript{Rn} have been subject to radioactive decay: \( A_t = A_0 e^{-\lambda t} \), wherein \( A_t \) represents the activity or mixing ratio of 222\textsuperscript{Rn} at a given time \( t \), \( A_0 \) is the original 222\textsuperscript{Rn} activity, \( t \) is the transit time of the air mass and \( \lambda \) is the decay constant (0.182 d\textsuperscript{-1}) of 222\textsuperscript{Rn}. The measured 222\textsuperscript{Rn} mixing ratio can be corrected for this decay by multiplying the measured 222\textsuperscript{Rn} mixing ratios individually with \( e^{\lambda t} \) when the transit time is known. In practice, the exact transit time and 222\textsuperscript{Rn} soil emission is usually not well-known. As a best estimate an average decay correction can be applied based on the average decay of the radon for the whole event and assuming a constant and homogeneously spread 222\textsuperscript{Rn} soil emission. Usually, Eq. (1) is therefore multiplied with \( e^{-\lambda t} \), with \( t \) being an estimated average transit time (Wilson et al., 1997; Gaudry et al., 1990; Schmidt et al., 2001; Schmidt et al., 2003) or based upon the total estimated transit time of 222\textsuperscript{Rn} above sea only (Biraud et al., 2000; Messager et al., 2008). The latter leads to an insufficient correction since 222\textsuperscript{Rn} also decays over land.

The main issue when correcting for decay lies in the estimation of the transit time of an air mass. When multiplying Eq. (1) with \( e^{-\lambda t} \) for example, we must be aware not to use the total time of duration of an event for \( t \) since all emissions from \( t = 0 \) to \( t < t_{\text{max}} \) will then be overcorrected resulting in an underestimation of the total CH\textsubscript{4} and N\textsubscript{2}O surface emissions. If one uses \( t_{\text{max}}/2 \) as an estimate for the average transit time for a given event, the error is minor but still this is principally incorrect as the radioactive decay does not follow a linear function.

Although the total transit time of an air mass from the emission’s source to our site is not well known, this transit time is the same for all air masses which are collected during the course of an event, assuming the atmospheric conditions do not alter significantly during the event. The emissions of CH\textsubscript{4} and N\textsubscript{2}O can then be calculated by multiplying Eq. (1) with:

\[
\frac{\int_0^{\tau_{\text{max}}} e^{-\lambda \tau} d\tau}{\tau_{\text{max}}} = \frac{-\lambda}{\tau_{\text{max}}} \left( e^{-\lambda \tau_{\text{max}}} - 1 \right) = \frac{1 - e^{-\lambda \tau_{\text{max}}}}{\lambda \cdot \tau_{\text{max}}} \quad (2)
\]

which is the average decay correction for the whole air mass.

For \( \tau_{\text{max}} = 5 \text{ days} \) the difference between (2) and a simple \( e^{-(1/2)\lambda \tau_{\text{max}}} \) correction is about 5%.

3.4 222\textsuperscript{Rn} soil flux estimations

For the 222\textsuperscript{Rn} soil flux of The Netherlands we used an average value of 0.29±0.10 atoms cm\textsuperscript{-2} s\textsuperscript{-1} as calculated by Szegvary (2007). These authors have created a European 222\textsuperscript{Rn} soil flux map based on the correlation of 222\textsuperscript{Rn} and gamma-dose rate measurements which were performed in 2006. Using this method they were able to use data from a high-density radiation monitoring network improving spatial data coverage. A large part of The Netherlands are coastal areas (North Sea in the west and the Wadden Sea in the North) and also there are many river deltas. Since these areas have a high moisture content the 222\textsuperscript{Rn} soil flux is lower in these parts compared to the parts in the south and the east of the country where the soil is more sandy and the groundwater table is lower. Szegvary (2007) found a spatial variation of ±0.10 atom cm\textsuperscript{-2} s\textsuperscript{-1} for The Netherlands. Since the 222\textsuperscript{Rn} soil flux is dependent on for example soil moisture, a temporal variation is expected in northern latitudes. However, below 55° N weekly averages were found to deviate less than 15% from the annual mean with no clear seasonal pattern (Szegvary, 2007).

For the events which were classified as long-range events an average soil flux of 0.59±0.27 atoms cm\textsuperscript{-2} s\textsuperscript{-1} was assumed which is the average of Belgium (0.65±0.14) atoms cm\textsuperscript{-2} s\textsuperscript{-1} and Germany (0.52±0.23) atoms cm\textsuperscript{-2} s\textsuperscript{-1} as calculated by Szegvary (2007).

4 Results

4.1 Short-range events

4.1.1 CH\textsubscript{4} emissions

In total 135 events passed our selection criteria and these are thus assumed to represent the emissions from The Netherlands from May 2006 to April 2009. The typical duration of an event was around 10 h. The results for the short range
Table 1. Comparison between the results from the radon flux method (May 2006 to April 2009) and the national inventories (averages of 2006 and 2007) of the Netherlands. The uncertainties in the measurements are the standard uncertainty and the uncertainty in the lognormal fit. The total combined uncertainty is based on the uncertainty of the $^{222}$Rn soil flux, the errors in the regression fits of the individual fluxes and the accuracy and precision of the $^{222}$Rn, CH$_4$ and N$_2$O measurements.

fluxes of CH$_4$ are shown in Fig. 6a. Most of the events are observed in the summer. This is expected since in winter the atmosphere can be stable for longer periods and long range events are more abundant. The dataset is therefore biased towards summertime CH$_4$ fluxes. The emissions are subject to a large variability, but no clear seasonality is observed. The emissions were corrected for $^{222}$Rn decay by about 4% (on average).

As explained in Sect. 3.2 we use a lognormal distribution to estimate the annual emissions, see Fig. 6b. The lognormal distribution fits the observations very well and we find annual CH$_4$ emissions for The Netherlands of (15.2±0.4)t km$^{-2}$ a$^{-1}$. This is 17% less than the (18.3±3.3)t km$^{-2}$ a$^{-1}$ given in the national reports. Our uncertainties are the standard uncertainties of the regression fit, not the total combined uncertainty in the annual estimation, this will be discussed later. The value of 18.3 t km$^{-2}$ a$^{-1}$ is the average value for 2006 and 2007 as given in the national reports. At the time of writing no estimate for 2008 was available. For comparison with previous studies we also give the results for the median and a Gaussian distribution fit. The median of the CH$_4$ emissions is 19.1 t km$^{-2}$ a$^{-1}$ and the mean of the monthly CH$_4$ averages is (22.7±1.6)t km$^{-2}$ a$^{-1}$, the latter being heavily influenced by the few very high fluxes. All final results are given in Table 1.

4.1.2 N$_2$O emissions

The fluxes of N$_2$O for the period of May 2006 to April 2009 are shown in Fig. 7a. In total 111 events passed our selection criteria and similar to CH$_4$, most of them occurred in the summer period. The largest fluxes appear to occur in the summer. The same correction for $^{222}$Rn decay was applied to the emissions of about 4% on average. Using the lognormal fit, the errors in the regression fits of the individual fluxes and the accuracy and precision of the $^{222}$Rn, CH$_4$ and N$_2$O measurements.

Fig. 7. (a) Fluxes of \( \text{N}_2\text{O} \) representative for emissions from the Netherlands. The error bars represent the \( \pm 1 \sigma \) uncertainties of the linear regression fits of the slopes. The value of the national inventories is indicated by the straight line. (b) Histogram of the \( \text{N}_2\text{O} \) fluxes with a lognormal fit. Fit quality is excellent \((R = 0.97)\). The arrows represent the values found using the lognormal approach \((1)\) and the national inventory \((2)\).

Fig. 8. (a) Concentration footprint of CH\(_4\) for the period of May 2006 to May 2008. Only long-range data were used. The highest mixing ratios are observed between 120\(^\circ\) and 240\(^\circ\) at wind speeds between 5 and 15 m s\(^{-1}\). The coastal line of N.W. Europe is clearly visible. (b) Similar to (a) but for \( \text{N}_2\text{O} \). The highest mixing ratios are observed at about the same wind direction as for CH\(_4\) but at lower wind speeds (around 5 m s\(^{-1}\)).

4.2 Long range events

As explained in Sect. 3.2 the long-range dataset contains a mixture of data which are not so clearly defined as the short-range events. In order to get an idea of the origin of the emissions the mixing ratios of CH\(_4\) (Fig. 8a) and \( \text{N}_2\text{O} \) (Fig. 8b) were plotted against the wind direction and wind speed for the period of May 2006 to April 2009. In Fig. 8a a clear distinction can be made between continental and oceanic air masses. The higher mixing ratios almost perfectly follow the coastal line—visualizing the mainland. The highest mixing ratios of CH\(_4\) are observed mostly between 120\(^\circ\) and 240\(^\circ\) at wind speeds between 5 and 15 m s\(^{-1}\). Possible sources of these emissions could be the German Ruhr basin \((150^\circ–170^\circ)\) at approx. 200 km distance from our station and the highly populated areas in the south of The Netherlands \((\text{approx. 200 km})\) and Belgium \((\text{approx. 300 km})\). In Fig. 8b the same exercise is performed for \( \text{N}_2\text{O} \). The highest mixing ratios are observed at about the same wind direction as for CH\(_4\) but at lower wind speeds (around 5 m s\(^{-1}\)). Also a source of \( \text{N}_2\text{O} \) is present at 270\(^\circ\), observed at wind speeds of about 15 m s\(^{-1}\). The relatively high mixing ratios, namely for \( \text{N}_2\text{O} \), observed at relative low wind speeds suggest that the observations are still influenced by emissions from The Netherlands.

In order to estimate fluxes from the long range dataset we excluded the marine sector and binned the data into monthly datasets from which the regression slopes and consequently the fluxes were determined. This implies that the lowest mixing ratio in the month is used as a baseline. Although it is virtually impossible to estimate an exact
Fig. 9. (a) Monthly averaged fluxes of CH$_4$ for the long-range dataset. The error bars represent the errors of the regressions fits of the individual slopes. The lines indicate the inventories of Germany (1) and Belgium (3). (b) Histogram of the long-range CH$_4$ fluxes with a lognormal fit. Fit quality is very good ($R = 0.94$). The arrows represent the values found using the lognormal approach (2) and the national inventories of Germany (1) and Belgium (3).

222$Rn$ decay correction we corrected our fluxes for a 33% loss, based on a transit time of 3 days. This is an educated guess based on observations of multiple-day events of 222$Rn$. We decided to not apply a regression coefficient filter on the long-range dataset since, in contrast to the short-range fluxes which were more or less attributable to individual sources or source areas, these monthly fluxes include mixing ratios from many different sources. Figure 9a shows the monthly averaged fluxes of CH$_4$ for the long-range dataset. Similar to our approach to the short-range fluxes we used a lognormal regression fit to estimate an annual emission rate, see Fig. 9b. With this method we find annual CH$_4$ emissions of $(8.9 \pm 0.3)\, t\, km^{-2}\, a^{-1}$. The median of the monthly averaged fluxes is $11.3\, km^{-2}\, a^{-1}$ and the mean is $13.4 \pm 1.5\, km^{-2}\, a^{-1}$. Figure 10a shows the monthly averaged fluxes of N$_2$O for the same period and these values are fitted with a lognormal regression fit, as shown in Fig. 10b. For N$_2$O we find an annual emission of $(4.2 \pm 0.3) \times 10^{-1}\, t\, km^{-2}\, a^{-1}$ using the lognormal approach. The median is $5.7 \times 10^{-1}\, t\, km^{-2}\, a^{-1}$ and the mean is $(6.5 \pm 0.6) \times 10^{-1}\, t\, km^{-2}\, a^{-1}$.

4.3 Uncertainty of the results

The uncertainties given in Sect. 4.1 and 4.2 are only the uncertainties of the lognormal fit and are not representative for the combined uncertainty in the estimates of the annual fluxes. The combined uncertainty is determined by the accuracy and precision of our measurements, the uncertainties in the individual regression slopes and mostly by the uncertainty in the value of the assumed (average) 222$Rn$ soil emission rate.

The smallest uncertainties lie in the measurements of the atmospheric mixing ratios of CH$_4$, N$_2$O and 222$Rn$. CH$_4$ and N$_2$O are measured with a gas chromatograph with an estimated combined uncertainty of about 0.8 ppb and 0.3 ppb respectively. The uncertainty of the ambient 222$Rn$ measurements is related to the amount of counts (per event) and the uncertainty in the 222$Rn$ source which is used to calibrate the device. The combined uncertainty of our 222$Rn$ measurements was about 5%.
The uncertainties in the linear regression fits of the slopes of \( \text{CH}_4 \) and \( \text{N}_2\text{O} \) vs. \( \text{Rn} \) were typically 10%. The main source of uncertainty concerning our final results lies in the assumption of the \( \text{Rn} \) soil flux, which we assumed to be constant for the whole measurement period. However, although the production of \( \text{Rn} \) in the soils is constant, its exhalation rate is also influenced by atmospheric pressure, soil temperature and soil humidity. This leads to a temporal variability of the net emissions which was estimated by Eckhardt (1990) to be in the order of \( \pm 20\% \). Furthermore, The Netherlands, although a very small country, has a large soil heterogeneity. Differences between the coastal areas and the southern inland part of the country can lead to differences in the \( \text{Rn} \) soil flux up to 30%. Taking these factors into account we estimate that our measurement-based annual emissions have a combined uncertainty of about \( \pm 35\% \). In Table 1 also the final results are given including an uncertainty of \( \pm 35\% \).

5 Discussion and conclusions

The method we used in this study is a valuable independent verification of the statistical approach usually applied for reporting the national emissions. The method is purely observation-based and almost independent of numerical models. There are, however, several uncertainties involved in this method. Although the calculated emissions are based on ambient measurements, we still rely on models to allocate the emissions to their source areas. In this study for example, we used a back trajectory model to filter out any events from our short-range dataset which appeared to be influenced (also) by emissions from abroad.

For the linear regression fits of the individual events we used a threshold of \( R > = 0.7 \). The results would be lower by 5% with \( R > = 0.6 \) and higher by 8% with \( R > = 0.8 \). The positive correlation could be caused by the fact that air masses containing emissions from very nearby are probably less disturbed and thus give a high correlation between \( \text{Rn} \) and \( \text{CH}_4 \) or \( \text{N}_2\text{O} \). Furthermore, these local (point) sources could be overestimated as the soil close to the tower has a relative high moisture content and therefore a lower radon soil flux compared to the average value of The Netherlands. Using a high \( R \) as a threshold value does therefore not necessary guarantee more reliable results (in terms of estimating national emissions).

The largest uncertainty lies in the translation of the mixing ratios of \( \text{CH}_4 \) and \( \text{N}_2\text{O} \) into their surface fluxes. In this study, a constant \( \text{Rn} \) surface emission rate was assumed based on a newly available European \( \text{Rn} \) soil emission map (Szegvary, 2007). In reality, the \( \text{Rn} \) surface emission rate can be affected at very small time scales (i.e. hours or days) by for example rain or snow. Although this will proportionally affect the calculated fluxes, we assume that the total uncertainty in our annual estimates due to this temporal variability is minor. The spatial variation of the \( \text{Rn} \) surface emission rate can be large, even for a small country as The Netherlands this amounts to about \( \pm 30\% \). Since the sources are not homogeneously distributed throughout the country this is also the potential uncertainty of the individual fluxes. The total uncertainty in the annual estimates due to the spatial variation of the \( \text{Rn} \) surface emission is probably less. A systematic error is introduced in the fluxes and the annual estimates if the average \( \text{Rn} \) surface emission rate is incorrect. Since the calculated surface emissions of \( \text{CH}_4 \) and \( \text{N}_2\text{O} \) are directly proportional to this applied \( \text{Rn} \) surface emission rate, any offset in its assumed value will be included in the final results. On the other hand, should more reliable data on \( \text{Rn} \) emissions become available, our values can be adjusted in a simple way.

The emissions which we classified as long-range data have additional factors of uncertainty because they consist of a mix of signals with different temporal and spatial resolution. It is therefore virtually impossible to estimate the \( \text{Rn} \) soil emission rate or determine a proper \( \text{Rn} \) decay correction. Basically, our long-range dataset can include all \( \text{Rn} \) mixing ratios older than the short-range data. A systematic error in the fluxes of about a factor of 2 is therefore possible. Furthermore, it is also not possible to exclude emissions from The Netherlands from the long range dataset. A long range event containing emissions from Germany or Belgium surely also picks up emissions from The Netherlands as it passes the country on its way to our measurement station. Since the \( \text{Rn} \) soil flux is almost 2 times lower in The Netherlands as compared to the neighbouring countries, Dutch emissions will be over-amplified by a factor of two when only applying non-Dutch soil emission rates. Consequently the absolute value of the annual flux of the long-range data will probably not be representative for the surface emissions of Germany and Belgium. Nevertheless, the method can still be valuable to assess long-term trends.

For The Netherlands, we found net emissions of: 15.2\( \pm 5.3 \, \text{t km}^{-2} \text{a}^{-1} \) for \( \text{CH}_4 \) and 0.9\( \pm 0.3 \, \text{t km}^{-2} \text{a}^{-1} \) for \( \text{N}_2\text{O} \). We compared our results to the national inventories (http://unfccc.int) as reported to the UNFCCC. Their uncertainties are estimated to be 18% for \( \text{CH}_4 \) and 45% for \( \text{N}_2\text{O} \) (Maas et al., 2008). We conclude that our estimates are only slightly lower than the inventory-based emissions (2006-2008 averages) of 18.3\( \pm 3.3 \, \text{t km}^{-2} \text{a}^{-1} \) for \( \text{CH}_4 \) and 1.3\( \pm 0.6 \, \text{t km}^{-2} \text{a}^{-1} \) for \( \text{N}_2\text{O} \) and well within the error margins of the inventories. Therefore, we further conclude that station Lutjewad is well suitable for the determination of the national emissions of \( \text{CH}_4 \) and \( \text{N}_2\text{O} \) and validation of the national inventories.

In a forthcoming paper, we will apply the same method to determine the fossil fuel \( \text{CO}_2 \) emissions of The Netherlands, and discuss our \( \text{Rn} \)-based flux methodology further.
